be understood from a resource allocation point of view. When resource intake becomes increasingly limiting, traits sharing the same resources will show an increasingly negative relationship [7, 8]. This perspective suggests that breeding for increased efficiency, which should be the overall goal of livestock genetic improvement [9], will lead to increasingly negative relationships between traits. From a genetic perspective, systematic trade-offs are the result of unfavorable pleiotropic effects of segregating genes. Sustained multitrait selection will increase such trade-offs because genes with favorable pleiotropic effects will become fixed by selection, while genes with unfavorable pleiotropic effects will remain segregating for much longer. There is no contradiction between the physiological and the genetic perspective; they merely represent different levels of causality. The evolutionary history of a population represents the ultimate level of causality because millions of years of evolution have shaped the biology of current livestock species. Hence, an evolutionary perspective may help to identify new opportunities for genetic improvement because it provides some understanding of the forces that have shaped the current livestock populations.

Denison et al. [10] consider opportunities for genetic improvement of agricultural populations from an evolutionary perspective. They argue that breeders cannot compete with the natural selection that has occurred in the evolutionary history of livestock populations because of the difference in time scales, being years for breeders and millions of years for natural selection. Consequently, it is unlikely that breeders can improve traits that have always been a target of natural selection. Typical examples are general disease resistance and basic efficiencies of metabolic processes. Hence, rather than trying to mimic natural selection, breeders should investigate other directions for genetic improvement.

A second reason why breeders should not try to mimic natural selection is that they have a fundamentally different objective. While natural selection acts on individual fitness, breeders are interested in the average performance of groups of animals or entire populations. Because natural selection acts on individual fitness, it has the intrinsic tendency to increase competition among population members. Thus natural selection may result in selfish individuals that are successful at the expense of others, rather than in maximization of output on the population, flock, or herd level. A clear example comes from the difference between wild wheat and rice versus modern cultivars. In natural populations, individual plants compete for sunlight. Natural varieties and traditional cultivars, therefore, have long stems making them sensitive to lodging (falling over). Modern wheat and rice cultivars, however, owe their high-yield potential largely to their short stature, relative to traditional cultivars. Short stature reduces lodging and increases growth of grain at the expense of stems, but artificial selection for these traits has resulted in decreased individual competitiveness. Forced to compete with traditional, low-yielding cultivars, modern high-yield rice cultivars completely disappear within as few as three generations [10]. This result clearly demonstrates that natural populations do not provide a useful blueprint for agriculture. Moreover, it illustrates the relevance of competition among individuals in natural populations, which may also be relevant for livestock genetic improvement.

Denison et al. [10], therefore, conclude that breeders should investigate directions of human interest that are not already exhausted by natural selection. They identify two such directions. First, since domestication has greatly changed the environment to which populations are exposed, certain traits that are essential in nature may no longer be useful in domestic populations. Thus this change in environment releases usable genetic variation. Most modern agricultural species do, e.g., not need the capacity to escape from predators, or to deal with seasonal starvation. Hence, to achieve progress in traits of human interest, breeders should provide good environments and accept sacrificing traits that are essential in natural populations, rather than trying to breed robust individuals that can deal with very challenging environments. This direction has already been exhausted to a great deal in livestock. Improvement of genetics, husbandry, and feeding have gone together ever since domestication, and classical selection strategies implicitly utilize the genetic variance released by improvement of the environment. This approach, however, is gradually reaching limits. Concerns about animal welfare are on the increase in Western societies, and producers sometimes have difficulty providing the environment allowing animals to express their full genetic potential

(personal communication Egbert Knol (IPG) and Frans van Sambeek (ISA)). Hence, breeders already utilize opportunities arising from improved environments, and it seems unlikely that current rates of genetic improvement can be accelerated by further improvement of the environment.

Second, Denison et al. [10] argue that breeders should target traits beneficial to the population but not to the individual expressing the trait. This is because natural selection acts on individual fitness and does, therefore, not exhaust the genetic variance in the social effect that individuals have on each other. Hence, they suggest breeding for decreased competition among population members. Thus the quantity of interest here is the heritable effect of an individual on the trait values of its group mates, known as the associative or indirect genetic [11, 12], rather than on its own trait value. Most livestock populations are kept in groups, ranging from cages of four laying hens, groups of moderate size in pigs and beef cattle in feed lots, to large flocks of broilers, sheep or beef cattle. In those systems, performance of individuals may depend on (social) characteristics of the other individuals present in the same group. Well-known examples are mortality due to cannibalistic behaviors in non-beak-trimmed laying hens [13], and tail biting and aggression at mixing in swine [14]. Results in pigs, moreover, indicate that growth rate is affected by heritable social effects, even in ad libitum feeding [15]. Also aquaculture species provide a typical example of social effects, where variation among individuals is often considerably increased due to competition for feed [16].

When trait values depend on social interactions among individuals, selection of the best individuals may cause the average performance of a population to decline, rather than increase. In non-beak-trimmed laying hens, for example, selection of the survivors has decreased survival in the next generation because the survivors had a negative heritable effect on survival of their cage mates [17]. Results in plant breeding, however, illustrate that selection for increased yield in the presence of social interactions can be successful. Properties of modern crops show that plant breeders have successfully improved yields by decreasing competition (see above). Reasons for this success may be that plant breeders are more aware of competition among individuals, and that breeding for reduced competition is much easier in plants. (Theory shows that selection between clonal plots exploits the full heritable variance in traits, including the component due to competition; see below and in [18]). In livestock breeding, in contrast, relatively little is known of the magnitude of associative effects. With the exception of maternal genetic effects, breeders have hardly attempted to utilize associative effects for genetic improvement (But see Muir's selection experiments; [17, 19–21]). Hence, there is a need for further research on the magnitude of associative effects in livestock populations.

At first glance, breeding for improved social effects may seem difficult to apply in practice because social effects will often be the result of certain behaviors that may be difficult to record. Breeding for improved behavior is rarely applied in modern breeding practice because recording behaviors is usually very labor intensive. [22], however, showed that heritable social effects can be estimated in a similar way as maternal genetic effects [23] without the need to record the behaviors underlying the associative effects. At present, flexible tools are available to estimate social genetic effects without the need to observe the traits underlying them (See section on "Estimation of Genetic Parameters" below). Hence, nowadays breeders have the opportunity to address improvement of social interactions in their improvement programs.

Whether or not social interactions are of interest to breeders will depend on the trait considered and on the environment in which individuals are kept. Selection experiments on mortality in non-beak-trimmed layers kept in cages illustrate the relevance of social genetic effects in that situation [17, 20, 21]. For non-beak-trimmed laying hens, Ellen et al. [24] found that more than half of the total heritable variation in survival days originated from social effects. Bergsma et al. [15] found that social genetic effects contribute to heritable variation in growth rate and feed intake in pigs. In contrast, results of Arango et al. [25] in growing pigs indicate that social genetic effects may be difficult to estimate and not deviate significantly from zero. At present, knowledge of the importance of social genetic effects in populations of livestock and fish is still limited. In aquaculture, the large size differences among individual fish indicate that competition is important and that it affects uniformity [16], but the heritable

effects underlying such competition are largely unknown. It would be interesting to see whether fish breeders can achieve something similar as plant breeders, who have effectively reduced competition among individuals in wheat [10]. Though social genetic effects may not always be important and may be difficult to utilize in some cases, the promising results observed in layer chickens should be sufficient incentive for further research in this area. Moreover, genetic improvement of productivity resulting from improved social interactions may cause less trade-offs in health and welfare traits because it may reduce energy waste rather than shifting resources from fitness traits toward production traits [17]. This chapter summarizes the quantitative genetic theory of socially affected traits, covering the basic models, expressions for response to selection, and estimation of genetic parameters.

Quantitative Genetics of Socially Affected Traits

Quantitative Genetic Model

Classical Model In classical quantitative genetics and animal breeding theory, individual phenotypic values, P, are modeled as the sum of a heritable component, A, known as breeding value, and a residual, E, known as environment (Table 1) [26, 27],

$$P = A + E \tag{1}$$

The breeding value is the sum of the so-called average effects of the genes of the individual on its phenotype [28, 29]. It represents the heritable

Socially Affected Traits, Inheritance and Genetic Improvement. Table 1 Notation key

Symbol	Meaning
P, A, h^2	Phenotypic value, breeding value, heritability
i, j, n	Focal individual, group mate of focal individual, group size
$P_{D,i}$, $P_{S,i}$	Direct effect of i, (full) associative effect of i
$A_{D,i}$, $A_{S,i}$	Direct genetic effect of i, associative genetic effect of i
$E_{D,i}$, $E_{S,i}$	Direct non-genetic effect of i, associative non-genetic effect of i
$A_{T,i}$, T^2	Total breeding value of i, relative heritable variance
$A_{M,i}$, $E_{M,i}$	Breeding value for maternal effect of i, non-genetic maternal effect of i
R	Response to selection
ρ, ρ_T	Traditional accuracy of selection, total accuracy of selection
ρ_D, ρ_S	Direct and social accuracy of selection
g, r	Degree of between-group selection, relatedness between group mates
r_f, τ	relatedness between candidate and relatives, intraclass correlation between relatives
$\sigma^2_{A_D}$, $\sigma^2_{A_S}$	Direct genetic variance, associative genetic variance
$\sigma_{A_{DS}}$, r_g	Covariance and correlation between direct and associative genetic effects
$\sigma_{E_{DS}}$, r_E	Covariance and correlation between direct and non-genetic associative effects
σ^2_P, $\sigma_{P_{DS}}$	Phenotypic variance, full covariance between direct and associative effects
$\sigma^2_{A_T}$	Total heritable variance
σ^2_g, σ^2_e	Between-group non-genetic variance, residual variance
d	Degree of dilution of associative effects with group size
N_f, m	Number of families, effective number of records per family
σ^2_z, σ^2_f, σ^2_e	Full variance of records, between-family variance, residual variance
SE, $n_{opt,x}$	Standard error, optimum family size for parameter x

component of an individual's phenotype, whereas the "environment" comprises all non-heritable effects, including the non-heritable genetic effects arising from dominance and epistasis.

The absolute magnitude of the heritable effects is measured by the variance of the breeding values, σ_A^2, known as the additive genetic variance. The relative magnitude of the heritable effects is measured by the heritability, the ratio of heritable variance over phenotypic variance [26, 27],

$$h^2 = \sigma_A^2/\sigma_P^2 \tag{2}$$

Heritability expresses the relative contribution of heritable effects to phenotypic variance among individuals, taking values from 0 through 1. In the classical model, heritability also has the natural interpretation as the regression coefficient of offspring phenotype on mean phenotype of the parents; it is the proportion of phenotypic superiority in the parents that is recovered in the offspring. In the context of selection experiments, this quantity is known as the realized heritability [26].

Social Model As summarized in the Introduction, individuals may affect each other's phenotypes. The "environmental" component of the phenotype, therefore, also includes effects of the social environment provided by other individuals that interact with the focal individual. In contrast to the physical environment, however, the social environment is biological in origin and may therefore contain a heritable component. Hence, the E-term in Eq. 1 may contain heritable components due to other individuals. Such heritable effects on trait values of others are known as indirect genetic effects in the evolutionary genetic literature [12, 30], and as associative effects or social effects in the animal breeding literature [11, 17, 31]. Associative effects are of interest to animal breeders because they are heritable and thus can contribute to response to selection. Hence, for socially affected traits, the classical model in Eq. 1 needs to be modified because it treats associative effects as part of the non-heritable environment [11]. Also the definition of heritable variance may be modified because the classical additive genetic variance excludes the contribution of associative effects.

In most livestock and aquaculture populations, individuals are kept in groups, and interactions among individuals occur within group. In a population consisting of groups of n individuals each, the phenotype of an individual can be expressed as the sum of a direct effect rooted in the individual itself, and the associative effects of each of its $n-1$ group mates [11],

$$P_i = P_{D,i} + \sum_{i \neq j}^{n-1} P_{S,j}, \tag{3}$$

where $P_{D,i}$ denotes the direct effect due to the focal individual i, $P_{S,j}$ the associative effect of its group mate j, and the summation is over the $n-1$ group mates of the focal individual. Both the direct and associative effect may be decomposed into a heritable component, A, and a non-heritable component, E. The phenotype, therefore, is the sum of the direct breeding value and direct environmental effect of the focal individual, and the summed associative breeding values and associative environmental effects of each of its $n-1$ group mates [11, Fig. 1a],

$$P_i = A_{D,i} + E_{D,i} + \sum_{i \neq j}^{n-1} A_{S,j} + \sum_{i \neq j}^{n-1} E_{S,j} \tag{4}$$

In this expression, $A_{D,i}$ is the direct breeding value (DBV) of individual i, and $A_{S,j}$ the associative breeding value (SBV) of its group mate j. The DBV corresponds to the classical (direct) breeding value, whereas the SBV is a generalization of a breeding value for maternal effect (See section on "A Special Case: Maternal Genetic Effects" below). An individual's DBV is the sum of the direct average effects of its genes, whereas its SBV is the sum of the associative effects of its genes. In total, the $A_{D,i} + \sum_{i \neq j}^{n-1} A_{S,j}$ is the best predictor of the phenotype of the focal individual from the average effects of its own genes and those in its group mates, obtained using the method of least squares [27–29, 32]. The $E_{D,i}$ and $E_{S,i}$ are the corresponding non-heritable effects ("environment").

At first glance, it seems that the summation in Eq. 4 implies additivity of associative effects, whereas, in reality, an individual's associative effect may depend on the individual it interacts with. For example, an individual may interact in a positive manner with a certain group mate, but have adverse effects on

Socially Affected Traits, Inheritance and Genetic Improvement. Figure 1
(**a**) The phenotype of individual 1 is the sum of its own direct effect plus the associative effects of its group mates, $P_1 = A_{D,1} + E_{D,1} + \sum_{j=2,3,4}\left(A_{S,j} + E_{S,j}\right)$. (**b**) The total breeding value of individual 1 is the sum of its heritable effects on all group members, including itself, $A_{T,1} = A_{D,1} + 3A_{S,1}$

other group mates. Equation 4, however, considers the average associative effect of a genotype, which is additive by definition. This is an analogy of the average effect of an allele in, e.g., a single locus model [26, 29]. In the presence of dominance, the effect of an allele depends on the other allele at the locus. Nevertheless, one can still define the average effect of an allele, which is the effect relative for heritable variance and response to selection (at least in the short term). Hence, Eq. 4 does not assume additivity of the social interactions, but focuses on the heritable component of these interactions.

Breeding Value The objective of livestock genetic improvement is to generate response to selection, that is, to genetically change the mean trait values of the population. For this purpose, an individual's quality is measured by its heritable effect on the mean trait value of the population. In the classical model, an individual's heritable effect on the population mean simply equals the classical breeding value, A, as defined in Eq. 1. With associative effects, an individual's full heritable effect on the mean trait value of the population is the sum of its direct heritable effect on its own phenotype, plus its social heritable effect on the phenotypes of its group mates. Hence, an individual's total breeding value may be defined as [31; Fig. 1b]

$$A_{T,i} = A_{D,i} + (n-1)A_{S,i} \tag{5}$$

In contrast to an individual's phenotype, its total breeding value is entirely a property of its own genes (Fig. 1a vs 1b). The total breeding value is a generalization of the classical breeding value and is the heritable property relevant for response to selection in socially affected traits. Taking the average phenotype of the population shows that response to selection equals the change in mean total breeding value,

$$R = \Delta\bar{A}_T \tag{6}$$

In contrast to the classical breeding value, however, the total breeding value contains a part that is not expressed in the individual's own phenotype, nor in the phenotypes of its offspring, but in the group mates of the individual and of its offspring.

Heritable Variance In the classical model, heritable variance equals the variance of the breeding values among individuals. By analogy, for socially affected traits, the total heritable variance may be defined as the variance in total breeding values among individuals [31],

$$\sigma^2_{A_T} = \sigma^2_{A_D} + 2(n-1)\sigma_{A_{DS}} + (n-1)^2\sigma^2_{A_S}, \tag{7}$$

where $\sigma^2_{A_D}$ is the variance in direct breeding values, $\sigma^2_{A_S}$ the variance in associative breeding values, and $\sigma_{A_{DS}}$ the covariance. The total heritable variance reflects the magnitude of the heritable differences among

individuals that determine the potential of the population to respond to selection (See section "Response to Selection" below). The $(n-1)^2\sigma^2_{A_S}$ term represents the heritable variance present in the social environment. This term shows that even small associative effects can substantially increase the total heritable variance, particularly when groups are large. (But see the section "The Effect of Group Size on Heritable Variance" below.) This may explain the rapid response to group selection observed by Muir [19, 21]. The term $2(n-1)\sigma_{A_{DS}}$ shows that a negative genetic covariance between direct and associative breeding values reduces the total heritable variance. With negative $\sigma_{A_{DS}}$, individuals with positive breeding values for their own phenotype have on average negative associative effects on the phenotypes of their group mates, and vice versa. Thus a negative $\sigma_{A_{DS}}$ may be interpreted as "heritable competition." Heritable competition, therefore, reduces total heritable variance and thus the potential of the population to respond to selection. Heritable cooperation ($\sigma_{A_{DS}} > 0$), in contrast, increases total heritable variance.

The $\sigma^2_{A_T}$ expresses heritable variance in absolute units. The interpretation of the magnitude of the heritable variation is facilitated by expressing heritable variance relative to phenotypic variance, analogous to classical heritability (Eq. 2). By analogy, for socially affected traits, the ratio of total heritable variance over phenotypic variance equals [15],

$$T^2 = \frac{\sigma^2_{A_T}}{\sigma^2_P} \tag{8}$$

A comparison of h^2 and T^2 reveals the proportional contribution of associative to heritable variance. When group members are unrelated, phenotypic variance equals

$$\sigma^2_{P_{r=0}} = \sigma^2_{A_D} + \sigma^2_{E_D} + (n-1)\left(\sigma^2_{A_S} + \sigma^2_{E_S}\right) \tag{9}$$

With associative effects, phenotypic variance depends on relatedness between group members [15, 33]. As a consequence, T^2 depends on relatedness between group members when using the realized phenotypic variance in Eq. 8, which is inconvenient for a standardized parameter. Hence, to achieve standardization, it is preferable to scale total heritable variance by the phenotypic variance for populations with unrelated group members, using $T^2 = \sigma^2_{A_T}/\sigma^2_{P_{r=0}}$, rather than using the realized phenotypic variance in Eq. 8.

Comparison of Eqs. 7 and 9 shows that total heritable variance, $\sigma^2_{A_T}$, is not a component of phenotypic variance, illustrating that an individual's total breeding value is not a component of its trait value (Eq. 4 vs Eq. 5). Because an individual's total breeding value is dispersed over multiple individuals, it is hidden to direct observation. As a consequence, total heritable variance may exceed phenotypic variance, and T^2 may take values greater than one, whereas classical heritability has an upper limit of one. When group members are unrelated, the difference between the genetic component of phenotypic variance and total heritable variance equals (personal communication J. Bruce Walsh)

$$\sigma^2_{A_T} - \sigma^2_P = (n-1)\left[2\sigma_{A_{DS}} + (n-2)\sigma^2_{A_S}\right], \tag{10}$$

illustrating that heritable variance may substantially exceed phenotypic variance particularly when groups are large. (But see the following section on "The Effect of Group Size".) Social interactions, therefore, result in hidden heritable variation. Empirical results indeed indicate that T^2 may considerably exceed h^2, but values greater than one have not been found so far (See Table 3 below). Note, however, that greater heritable variance than phenotypic variance does not necessarily imply that associative effects increase response to selection. Whether or not the available heritable variance translates into response to selection depends on selection criterion and on relatedness between group members [11, 18, 33] (See section on "Response to Selection" below).

The Effect of Group Size on Heritable Variance The careful reader will have noted that total heritable variance approaches infinity when groups become large (Eq. 7), which is unrealistic. Indeed, when $\sigma^2_{A_S}$ remains constant while group size increases, the $\sigma^2_{A_T}$ in Eq. 7 increases continuously. The magnitude of the associative genetic variance, $\sigma^2_{A_S}$, however, will probably also depend on group size because interactions between a specific pair of individuals are likely to be less intense in large groups [25]. The relationship between the magnitude of associative effects and group size is

relevant because it affects the dynamics of response to selection, heritable variance, and group size. It determines, for example, whether or not selection is more efficient with larger groups.

Models accounting for the relationship between group size and associative effects have been provided in Refs. [25, 42, 43]. In [43], the relationship between associative effects and group size is modeled as

$$A_{S,i,n} = \left(\frac{\bar{n}-1}{n-1}\right)^{d} A_{S,i,\bar{n}}, \tag{11}$$

where $A_{S,i,n}$ is the associative effect of individual i when it would be expressed in a group of n members, $A_{S,i,\bar{n}}$ the associative effect of i when expressed in a group of the average size, $\bar{n}$, and d the degree of dilution. The degree of dilution measures the decrease of an individual's associative effect when group size increases.

With no dilution, $d = 0$, an individual's associative effect is the same for all group sizes, $A_{S,i,n} = A_{S,i,\bar{n}}$, so that its total associative effect summed over all group mates is proportional to the number of group mates, $(n-1)A_{S,i,n} = (n-1)A_{S,i,\bar{n}}$. This may occur, for example, in trees, where a large tree's associative effect may result from shading all individuals under its canopy, the effect on each individual being independent of the total number of individuals under the canopy (personal communication J. Bruce Walsh). With full dilution, $d = 1$, in contrast, an individual's total associative effect summed over all group mates is independent of group size, $(n-1)A_{S,i,n} = (\bar{n}-1)A_{S,i,\bar{n}}$, while its associative effect on each individual group mate is inversely proportional to the number of group mates, $A_{S,i,n} = [(\bar{n}-1)/(n-1)]\ A_{S,i,\bar{n}}$. This may occur, for example, with restricted feeding on group level, where an individual consuming 1 kg of feed has a total associative effect of -1 kg, and an average associative effect of $A_{S,i,n} = -1/(n-1)$ kg on each of its group mates. More generally, the magnitude of associative effects may be modeled as a function of the intensity of the interaction. In trees, for example, the associative effect of one tree on another may be modeled inversely proportional to the distance between both trees [17]. The degree of dilution of associative effects is an empirical issue, which may be trait and population specific, and needs to be estimated for the population of interest (See section on "Estimation of Genetic Parameters" below).

Dilution of associative effects alters the relationship between genetic variances and group size. The associative genetic variance for groups of $n$members equals,

$$\sigma^2_{A_S,n} = \left(\frac{\bar{n}-1}{n-1}\right)^{2d} \sigma^2_{A_S,\bar{n}}, \tag{12}$$

which decreases with group size for $d > 0$. The total heritable variance for groups of n members equals

$$\begin{aligned}\sigma^2_{A_T,n} = \sigma^2_{A_D} + 2(\bar{n}-1)^{d}(n-1)^{1-d}\sigma_{A_{DS},\bar{n}} \\ +(\bar{n}-1)^{2d}(n-1)^{2-2d}\sigma^2_{A_S,\bar{n}}\end{aligned} \tag{13}$$

(This expression may seem complex, but note that $\bar{n}$ is a constant for any particular population). Hence, for $\sigma_{A_{DS}} = 0$, total heritable variance increases with group size as long as dilution is incomplete ($d < 1$), and total heritable variance is independent of group size with full dilution ($d = 1$). Since total heritable variance depends on group size and on the degree of dilution, response to selection will also depend on those factors. To account for the effect of dilution on response to selection, the $\sigma^2_{A_S}$ and $\sigma^2_{A_T}$ should be substituted by Eqs. 12 and 13 in the expressions for response to selection provided below.

When genetic and non-genetic associative effects show the same dilution with group size, the phenotypic variance in populations of groups of $n$unrelated members equals

$$\sigma^2_{P,n} = \sigma^2_{P_D} + (\bar{n}-1)^{2d}(n-1)^{1-2d}\sigma^2_{P_S,\bar{n}} \tag{14}$$

showing that phenotypic variance increases with group size for $d < 0.5$, is independent of group size for $d = 0.5$, and decreases with group size for $d > 0.5$. Hence, the relationship between phenotypic variance and group size provides an approximate impression of the degree of dilution.

Response to Selection

In a series of papers, Griffing [11, 33, 44–46] showed theoretically that associative effects on trait values alter response to genetic selection, not only in magnitude but potentially also in direction, and demonstrated that response depends strongly on relatedness among interacting individuals and on the selection criterion. Results of Griffing, however, do not fit easily in the common animal breeding framework for response to

selection and have largely been overlooked. Griffing [44] summarized his results into a more common theoretical framework, but this work was published in a conference proceeding and was also largely overlooked. Muir [17] and Bijma et al. [31] rediscovered those results and expressed them in terms familiar to animal breeders. This section summarizes the resulting expressions for response to artificial selection, accounting for associative effects, genetic relatedness among interacting individuals, and selection acting on multiple levels, such as individual or group, or on an (optimum) index of both.

General Expression for Response to Selection In classical animal breeding theory, i.e., in the absence of associative effects, response to selection is commonly expressed as the product of the intensity of selection, $\imath$, the accuracy of selection, ρ, and the additive genetic standard deviation in the trait, σ_A [e.g., 47],

$$R = \imath\rho\sigma_A \tag{15}$$

In this expression, R is the genetic change in mean trait value from one generation to the next. The selection intensity expresses the phenotypic superiority of the selected parents in standard deviation units, $i = S/\sigma$, where S is the superiority of the selected parents for the selection criterion and σ is the standard deviation of the selection criterion among the candidates for selection. The accuracy is the correlation between the value of the selection criterion (SC) and the additive genetic merit for the trait (the breeding value) in the candidates for selection,

$$\rho = \mathrm{corr}(A, \mathrm{SC}) \tag{16}$$

Equation 15 partitions response to selection into three clearly distinct components; a scale-free measure of the strength of selection, $\imath$, a scale-free measure of how accurately the selection criterion resembles an individual's true breeding value for the trait of interest, ρ, and a measure of the magnitude of the heritable differences in the population, σ_A. The intensity of selection is largely determined by the reproductive potential of the species and the availability of reproductive technologies such as artificial insemination. The accuracy reflects the quality of the selection criterion, which depends on the type and amount of information collected. The genetic standard deviation is an intrinsic biological property of the population, reflecting its potential to respond to selection, and is outside human control. (Equation 15 can easily be extended to account for two sexes [26]).

The classical expression for response can be generalized to account for associative effects [48]. From the trait model (Eq. 4), it follows that response to selection equals the increase in mean direct breeding value plus the increase in mean associative breeding value weighted by the number of group mates, $R = \Delta[\bar{A}_D + (n-1)\bar{A}_S]$, which is the change in mean total breeding value, $\Delta\bar{A}_T$ (Eq. 5). The change in mean total breeding value equals the mean total breeding value of the selected parents expressed as a deviation from the overall mean and follows from regression of the total breeding value on the selection criterion, $R = b_{A_T,\mathrm{SC}}(\mathrm{SC} - \overline{\mathrm{SC}})$. From the definitions of regression and correlation coefficients, and using $\mathrm{SC} - \overline{\mathrm{SC}} = \imath\sigma_{\mathrm{SC}}$, it follows that

$$R = \imath\rho_T\sigma_{A_T}, \tag{17}$$

where the total accuracy of selection, ρ_T, is the correlation between the selection criterion and the total breeding value in the candidates for selection, and σ_{A_T} is the total genetic standard deviation in the trait (Eq. 7). Equation 17 applies to any selection strategy and inheritance model, as long as the total breeding value represents the average effects of an individual's genes on the mean trait value of the population. (See [49] for an application to maternal effects, and [49] for an application to both associative and maternal effects). Equation 17 corresponds to the first term of Price's Theorem [50] and represents the change in trait value due to change in allele frequency, keeping average effects of alleles constant for all elements of the inheritance model. Because intensity and accuracy are scale-free parameters depending on the breeding design, the total genetic standard deviation reflects the intrinsic potential of a population to respond to selection. Thus the total heritable variance defined in Eq. 7 bears a direct relationship to response to selection. In theory, σ_{A_T} may exceed σ_P (see above), suggesting that response in socially affected traits can be very large relative to phenotypic standard deviation. While this agrees with the very large response observed by Muir [19, 21] in cannibalistic laying hens, it is unlikely that

this phenomenon is widespread in livestock. Nevertheless, the potential for genetic improvement of socially affected traits may be larger than suggested by classical theory (see Table 3 below).

Accuracies of Selection Traditional selection methods include mass selection, selection based on information recorded on relatives, mostly full sibs, half sibs, or progeny, index selection [51, 52], and selection on estimated breeding values (EBV) obtained using Best Linear Unbiased Prediction (BLUP, [53]). Those methods are aimed at the classical (direct) breeding value and do therefore not fully utilize the available heritable variation when trait values are affected by associative effects. Efficient improvement of socially affected traits, therefore, requires modification of classical selection methods. Research in the field of evolutionary biology [12, 18, 30, 54–57] and early work on associative effects [11, 33] indicates that genetic relatedness among interacting individuals and selection acting on the group rather than the individual level strongly affect response to selection. Relatedness between group members and selection between groups are, therefore, important factors in response to selection for socially affected traits.

The following summarizes the accuracies for direct, associative, and total breeding value for a number of selection strategies (Table 2). In all cases, the individuals that provide the information for selection are kept in groups of n members, but the selection criterion may differ. For any parameter, response to selection is the product of intensity ($\imath$), accuracy (ρ), and genetic standard deviation (σ_A) for the parameter of interest,

$$R_D = \imath \rho_D \sigma_{A_D} \tag{18a}$$

$$R_S = \imath \rho_S \sigma_{A_S} \tag{18b}$$

$$R = R_D + (n-1)R_S = \imath \rho_T \sigma_{A_T} \tag{18c}$$

Individual Selection (IS) With individual selection (also known as "mass selection"), the individuals with the best phenotypes are selected as parents of the next generation. The total accuracy of individual selection equals (Ellen et al. 2007),

$$\rho_{T,\mathrm{IS}} = \frac{r\,\sigma^2_{A_T} + (1-r)[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]}{\sigma_{A_T}\sigma_P} \tag{19}$$

In the numerator of Eq. 19, relatedness acts as a weighting factor; greater relatedness increases the $\sigma^2_{A_T}$ term, while decreasing the $\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}$ term (Fig. 2a).

When group members are unrelated, IS does not directly target the associative breeding value, as illustrated by the accuracy of associative effects, $\rho_{S,\mathrm{IS}}(r=0) = \sigma_{A_{DS}}/(\sigma_{A_S}\sigma_P)$ (Table 2). Hence, when group member are unrelated, response in associative effects is entirely dependent on the covariance between direct and associative effects (Fig. 2b). When this covariance is negative, IS yields a negative response in associative effects, meaning that competition among individuals increases. Moreover, with unrelated group members, the negative response in associative effects may exceed the positive response in direct effect, $-(n-1)R_S > R_D$, yielding a negative net response and a negative total accuracy. This occurs when $\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}} < 0$. The risk of negative response is not merely a theoretical possibility, but has been observed for egg number in cannibalistic laying hens by Muir [17].

When relatedness between group members increases, components in the numerator shift away from a potentially negative term, $\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}$, toward a positive term, $\sigma^2_{A_T}$, which increases the accuracy (Fig. 2a). In the extreme case with fully related group members (clones), $\rho_{T,\mathrm{IS}}(r=1) = \sigma_{A_T}/\sigma_P$, which is an analogy of the classical accuracy of individual selection, $\rho_{\mathrm{mass}} = h = \sigma_A/\sigma_P$ [26]. This illustrates that a population consisting of clone groups is genetically equivalent to a population consisting of noninteracting individuals with heritability $h^2 = \sigma^2_{A_T}/\sigma^2_P$. In other words, the "group becomes an individual" when group members are fully related. In summary, with individual selection, relatedness between group members can prevent negative accuracies.

Group Selection (GS) With group selection, selection is based solely on mean trait values of the groups, so that parents are selected from the best groups [33, 58, 59]. The accuracy of group selection equals [48]

$$\rho_{T,\mathrm{GS}} = \frac{[1+(n-1)r]\sigma_{A_T}}{n\sigma_{\bar{P}}}, \tag{20a}$$

where $\sigma_{\bar{P}}$ is the standard deviation of the group means,

Socially Affected Traits, Inheritance and Genetic Improvement. Table 2 Accuracies of selection

		Total	Direct	Associative
IS[a]	$r = 0$	$\frac{\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}}{\sigma_P \sigma_{A_T}}$	$\frac{\sigma_{A_D}}{\sigma_P}$	$\frac{\sigma_{A_{DS}}}{\sigma_P \sigma_{A_S}}$
	$r \neq 0$	$\frac{r\,\sigma^2_{A_T} + (1-r)[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]}{\sigma_{A_T}\sigma_P}$	$\frac{\sigma^2_{A_D} + r(n-1)\sigma_{A_{DS}}}{\sigma_{A_D}\sigma_P}$	$\frac{\sigma_{A_{DS}} + r(n-1)\sigma^2_{A_S}}{\sigma_{A_S}\sigma_P}$

	$r = r_w$[f]	$\frac{r\sigma_{A_T}}{\sigma_{\bar{P}_f}} = \frac{r_f\eta}{\sqrt{\tau + (1-\tau)/mn}}$	$\frac{r_f[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]}{\sigma_{A_D}\sigma_{\bar{P}_f}}$	$\frac{r_f[\sigma_{A_{DS}} + (n-1)\sigma^2_{A_S}]}{\sigma_{A_S}\sigma_{\bar{P}_f}}$

[a]Individual selection.
[b]Group selection; $\sigma_{\bar{P}}$ is the standard deviation of the group means (Eq. 20b).
[c]Index selection, $I_i = P_i + g\sum_{n-1} P_j$, g represents the degree of group selection, σ_I is the standard deviation of the index.
[d]Selection based on phenotypes of relatives; r_f is the additive genetic relatedness between the candidate and the relatives providing information, which equals 0.25 for half sibs, and 0.5 for full sibs and progeny; $\sigma_{\bar{P}_f}$ is the standard deviation of the family mean.
[e]The relatives of the selection candidate are mixed at random over groups, so that group members are on average unrelated.
[f]The relatives of selection candidates are kept together in groups, so that relatedness within groups equals within-family relatedness (r_w), which equals 0.25 for half sib families and 0.5 for full sib families. The m is the number of groups of relatives per candidate, so that mn is the total number of relatives per candidates. See Eq. 35 for η and τ.

Socially Affected Traits, Inheritance and Genetic Improvement. Figure 2
Accuracies of mass selection. (**a**) Total accuracy. *No symbols*: $r_{A_{DS}} = -0.5$; *boxes*: $r_{A_{DS}} = 0$; *crosses*: $r_{A_{DS}} = +0.5$. (**b**) Direct and associative accuracies. *Solid lines*: direct accuracy; *dotted lines*: associative accuracy. Symbols as in panel **a**. Other genetic parameters are $n = 8$, $\sigma^2_{A_D} = 1.5$, $\sigma^2_{A_S} = 0.05$, $h^2_D = h^2_S = 0.3$ and $r_{E_{DS}} = r_{A_{DS}}$. These parameters yield a phenotypic variance of $\sigma^2_P = 6.17$ when relatedness equals zero, and total heritable variances of $\sigma^2_{A_T} = 2.03$ for $r_{A_{DS}} = -0.5$, $\sigma^2_{A_T} = 3.95$ for $r_{A_{DS}} = 0$, and $\sigma^2_{A_T} = 5.87$ for $r_{A_{DS}} = +0.5$, respectively

$$\sigma^2_{\bar{P}} = \frac{1}{n}\left[\sigma^2_P + (n-1)\mathrm{Cov}(P_i, P_j)\right] \tag{20b}$$

in which $\mathrm{Cov}(P_i, P_j)$ is the covariance between the phenotypes of two group members,

$$\begin{aligned}\mathrm{Cov}(P_i, P_j) = {} & 2\sigma_{P_{DS}} + (n-2)\sigma^2_{P_S} \\ & + r\left[\sigma^2_{A_D} + 2(n-2)\sigma_{A_{DS}}\right. \\ & \left. + (n^2 - 3n + 3)\sigma^2_{A_S}\right].\end{aligned} \tag{20c}$$

Because both the numerator and denominator of Eq. 20a are nonnegative, accuracy of group selection is nonnegative, irrespective of relatedness. Accuracy of GS has lower limit of zero, which occurs when all groups are composed in exactly the same manner; for example, when 10 clones are allocated to 10 groups, each group containing precisely one individual of each clone. In that case, $r = -1/(n-1)$ and accuracy is zero [60]. In this case, there is no between-group genetic variance, so that group selection cannot create response. In all other cases, GS directly targets the total breeding value, as illustrated by the σ_{A_T} in the numerator of Eq. 20a. This is because an individual's total breeding value surfaces in the group mean; the direct breeding value via its own phenotype and the associative breeding value via the phenotypes of each of its $(n-1)$ group mates. Group selection, therefore, also directly targets both direct and associative breeding values, as illustrated by the $\sigma^2_{A_D}$ and $\sigma^2_{A_S}$ in the numerator of the direct and associative accuracy, respectively (Table 2).

When group members are unrelated, however, the n in the denominator causes accuracy to be low particularly when groups are large. This is because the between-group genetic variance is proportional to $1/n$ when group members are unrelated. Hence, with unrelated group members, the genetic variance that can be utilized by group selection decreases with group size, and approaches zero for large groups. Relatedness between group members considerably increases the accuracy of group selection because it increases the between-group genetic variance. In the extreme case of fully related group members (clones), $\rho_{T,\mathrm{GS}}(r = 1) = \sigma_{A_T}/\sigma_{\bar{P}}$, which may be interpreted as the square root of the group heritability, $\sigma^2_{A_T}/\sigma^2_{\bar{P}}$. Note that GS outperforms IS when group members are fully related because $\sigma_{A_T}/\sigma_{\bar{P}} > \sigma_{A_T}/\sigma_P$. This occurs because GS does not waste effort on within-group selection, which is useless when group members are genetically identical. In summary, group selection prevents negative accuracy, but is efficient only when group members are sufficiently related.

Multilevel Selection Rather than selecting solely on individual or mean group phenotype, one may select on a linear combination of phenotypes of group mates and individual phenotype. In terminology used in evolutionary biology, this is an application of multilevel selection, where the levels of selection are the individual and the group. In natural populations, multilevel selection occurs when individual fitness depends on both properties of the individual itself and on properties of its groups. Multilevel selection is widespread in nature [61], but can also be applied as a breeding strategy in livestock and aquaculture [17, 31, 44].

Multilevel selection may be described by the following index [17, 31, 44]

$$I_i = P_i + g\sum_{n-1} P_j \tag{21}$$

where g represents the weight on the summed phenotypes of the $(n-1)$ group mates. A $g = 0$ corresponds to individual selection, whereas a $g = 1$ corresponds to selection on $I_{i,g=1} = \sum_n P_j$, where the summation is over all $n$group members, including the individual of interest. Hence, a $g = 1$ corresponds to between-group selection. Thus the $g$may be interpreted as a measure of the degree of group versus individual selection. A $g = -1/(n-1)$ corresponds to within-group selection, where individuals are selected based on the deviation of their phenotype from the mean phenotype of their group. (Interestingly, the value of $-1/(n-1)$ is also the lower bound for relatedness between group members, indicating a symmetry between $g$and r; [60]).

The accuracy of multilevel selection equals [62]

$$\rho_{T,I} = \frac{[g + r + (n-2)gr]\,\sigma^2_{A_T} + (1-g)(1-r)[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]}{\sigma_{A_T}\sigma_I} \tag{22}$$

Note that the numerator of this expression is fully symmetric in the degree of group selection, g, and relatedness, r, indicating that group selection and relatedness have precisely the same effect on the covariance between the index value and the total breeding value of selection candidates. The first term in the numerator, $[g + r + (n-2)gr]\,\sigma^2_{A_T}$, shows that group selection and relatedness cause selection to target the total breeding value. The second term, $(1-g)(1-r)[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]$, shows that the complement of group selection and relatedness acts on a term that is potentially negative. The $[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]$ is the numerator of the accuracy of individual selection with unrelated group members, which may indeed give negative response (See section on "Individual Selection" above). Hence, group selection and relatedness shift selection away from a potentially negative term toward the total genetic variance, thereby preventing negative response due to increased competition. Figure 3a illustrates this effect, showing that the combination of multilevel selection and relatedness may strongly increase accuracy. When group members are unrelated, the effect of multilevel selection on accuracy may be only moderate, and an intermediate value of $g$may be optimal. Figure 3b shows that multilevel selection and relatedness increase the accuracy of the associative effect, which may be at the expense of the direct effect when the direct-associative genetic correlation is negative.

Optimum Index Selection If the genetic parameters of direct and associative effects are known, then the degree of between-group selection, g, can be optimized using selection index theory [17, 44, 48, 51]. For this purpose, it is convenient to rescale the index to

$$I_i = b_1 P_i + b_2 \sum_{n-1} P_j \tag{23}$$

This index is equivalent to $I_i = P_i + (b_2/b_1)\sum_{n-1} P_j$, so that the optimum degree of group selection is

$$g_{\text{opt}} = \frac{b_{2,\text{opt}}}{b_{1,\text{opt}}} \tag{24}$$

From selection index theory, optimum index weights are [52]

$$\mathbf{b}_{\text{opt}} = \mathbf{P}^{-1}\mathbf{G}\mathbf{v}, \tag{25}$$

where $\mathbf{b}_{\text{opt}}$ is a column-vector of optimum index weights, $\mathbf{b}'_{\text{opt}} = [\,b_{1,\text{opt}} \quad b_{2,\text{opt}}\,]$, $\mathbf{P}$ is the symmetric matrix of covariances between the information sources in the index,

$$\mathbf{P} = \begin{bmatrix} \text{Var}(P_i) & \text{Cov}\left(P_i, \sum_{n-1} P_j\right) \\ \text{Cov}\left(P_i, \sum_{n-1} P_j\right) & \text{Var}\left(\sum_{n-1} P_j\right) \end{bmatrix},$$

Socially Affected Traits, Inheritance and Genetic Improvement. Figure 3
Accuracy of multilevel selection, $I_i = P_i + g\sum_{n-1} P_j$. (**a**) Total accuracy. *No symbols*: $g = 0$, $r \in [0, 1]$; *boxes*: $r = 0$, $g \in [0, 1]$; crosses: $r = g \in [0, 1]$. (**b**) Direct and associative accuracies. *Solid lines*: direct accuracy; *dotted lines*: associative accuracy. Symbols as in panel **a**. Other genetic parameters are $n = 8$, $\sigma^2_{A_D} = 1.5$, $\sigma^2_{A_S} = 0.05$, $r_{A_{DS}} = -0.5$, $h^2_D = h^2_S = 0.3$ and $r_{E_{DS}} = r_{A_{DS}}$. These parameters yield a phenotypic variance of $\sigma^2_P = 6.17$ when relatedness equals zero, and a total heritable variance of $\sigma^2_{A_T} = 2.03$

G is the matrix of covariances between the information sources in the index (rows of **G**) and the true direct and associative breeding values of the individual of interest (columns of **G**),

$$\mathbf{G} = \begin{bmatrix} \mathrm{Cov}(P_i, A_{D,i}) & \mathrm{Cov}(P_i, A_{S,i}) \\ \mathrm{Cov}\left(\sum_{n-1} P_j, A_{D,i}\right) & \mathrm{Cov}\left(\sum_{n-1} P_j, A_{S,i}\right) \end{bmatrix},$$

and **v** is a vector of weights on direct and associative breeding values (also known as "economic values"). Because response equals $R = \Delta[A_D + (n-1)A_S]$, the weights required to optimize response to selection are given by $\mathbf{v}' = [1 n - 1]$.

Elements of **P** are

$$P_{11} = \sigma^2_P \tag{26a}$$

$$P_{12} = P_{21} = (n-1)\mathrm{Cov}(P_i, P_j) \tag{26b}$$

$$P_{22} = (n-1)\mathrm{Var}(P_i) + (n-1)(n-2)\mathrm{Cov}(P_i, P_j), \tag{26c}$$

where $\mathrm{Cov}(P_i, P_j)$ is the covariance between the phenotypes of two group members, which equals

$$\mathrm{Cov}(P_i, P_j) = 2\sigma_{P_{DS}} + (n-2)\sigma^2_{P_S} + r\left[\sigma^2_{A_D} + 2(n-2)\sigma_{A_{DS}} + (n^2 - 3n + 3)\sigma^2_{A_S}\right]. \tag{27}$$

The first two terms of this expression can be obtained from mixed model analysis using, $2\sigma_{P_{DS}} + (n-2)\sigma^2_{P_S} = 2\sigma_{A_{DS}} + (n-2)\sigma^2_{A_S} + \sigma^2_g$, where σ^2_g is the between-group non-genetic variance (See section "Estimation of Genetic Parameters" below). Elements of **G** are

$$G_{11} = \sigma^2_{A_D} + (n-1)r\sigma_{A_{DS}} \tag{28a}$$

$$G_{12} = \sigma_{A_{DS}} + (n-1)r\sigma^2_{A_S} \tag{28b}$$

$$G_{21} = (n-1)\left[r\sigma^2_{A_D} + \sigma_{A_{DS}} + (n-2)r\sigma_{A_{DS}}\right] \tag{28c}$$

$$G_{22} = (n-1)\left[r\sigma_{A_{DS}} + \sigma^2_{A_S} + (n-2)r\sigma^2_{A_S}\right] \tag{28d}$$

Using those **P** and **G**, the optimum weight on group versus individual, g_{opt}, follows from Eqs. 25 and 24. Note that g_{opt} may fall outside the 0–1 range. For

example, when associative effects are large, g_{opt} may exceed one, indicating that the individual phenotype is weighted negatively relative to the overall group mean.

The accuracy of the optimum index can be obtained either by substituting g_{opt} into Eq. 22, or from

$$\rho_{T,I_{opt}} = \sigma_I / \sigma_{A_T}, \tag{29}$$

where σ_I is the standard deviation of the index,

$$\sigma_I = \sqrt{\mathbf{b}'\mathbf{P}\mathbf{b}} \tag{30}$$

For any index, i.e., for any combination of weights on the phenotype of the individual versus the summed phenotypes of its group mates, accuracy is given by

$$\rho_T(\mathbf{b}) = \frac{\mathbf{b}'\mathbf{G}\mathbf{v}}{\sigma_I \sigma_{A_T}} \tag{31}$$

This expression is equivalent to Eq. 22, where $g = b_2/b_1$. Total response to selection follows from Eq. 17, and responses in direct and associative effects are given by

$$\begin{bmatrix} \Delta\bar{A}_D \\ \Delta\bar{A}_S \end{bmatrix} = \mathbf{b}'\mathbf{G}\frac{\imath}{\sigma_I}, \tag{32}$$

where $\imath$ is the intensity of selection [26].

Figure 4 illustrates the accuracy of index selection, showing that accuracy is always positive and increases considerably with relatedness among group members. Hence, also when index weights are optimized, there is still a clear benefit of using groups composed of related group members. This result extends to selection on estimated breeding values using best linear unbiased prediction (see below).

Socially Affected Traits, Inheritance and Genetic Improvement. Figure 4
Accuracy of an optimum index of own performance and group mates, $I = b_1 P_i + b_2 \sum_{n-1} P_j$, as a function of relatedness among group members. For three genetic correlations between direct and associative effects; *dashed line* $r_{A_{DS}} = -0.5$, *dotted line* $r_{A_{DS}} = 0$, *solid line* $r_{A_{DS}} = +0.5$. Other genetic parameters are $n = 8$, $\sigma^2_{A_D} = 1.5$, $\sigma^2_{A_S} = 0.05$, $h^2_D = h^2_S = 0.3$ and $r_{E_{DS}} = r_{A_{DS}}$. These parameters yield a phenotypic variance of $\sigma^2_P = 6.17$ when relatedness equals zero, and total heritable variances of $\sigma^2_{A_T} = 2.03$ for $r_{A_{DS}} = -0.5$, $\sigma^2_{A_T} = 3.95$ for $r_{A_{DS}} = 0$, and $\sigma^2_{A_T} = 5.87$ for $r_{A_{DS}} = +0.5$, respectively

Selection Based in Information of Relatives The above-mentioned selection methods rely on phenotypic information collected on the selection candidates themselves, which requires that the selection candidates are kept in groups (When selection candidates are housed individually, their phenotypes provide no information on their associative effect). Keeping selection candidates in groups, however, is often undesirable or difficult to apply in practice, particularly in laying hens and broilers. This is because group housing may interfere with recording data on an individual basis for important traits such as egg number or individual feed intake. Moreover, for behavioral traits such as cannibalism, group housing may increase loss of selection candidates which is costly and reduces the intensity of selection. Also for veterinary reasons, it is often required that selection candidates are kept in clean conditions, such as Specific Pathogen Free environments, which are very different from the average production environment. Hence, response to selection based on information collected on the candidates themselves may be sensitive to genotype by environment interaction. Finally, recording of certain traits, such as carcass quality, may require sacrificing the individual, in which case selection cannot be based on own performance information.

For those reasons, selection decisions are often based on phenotypic information collected on relatives

of the selection candidates, particularly sibs or progeny. Ideally, those relatives are kept in environments resembling commercial production environments, such as group housing and increased levels of disease. The following provides expressions for response to selection in socially affected traits when selection decisions are based on phenotypes of relatives kept in groups [48].

Consider selection on the average phenotype of relatives of the selection candidate, $\bar{P}_{\text{rels}}$. The phenotypic value of a relative j consists of the direct effect of j, and the summed associative effects of its group mates, $P_j = P_{D_j} + \sum_{n-1} P_{S_k}$, k denoting a group mate. When the group mates of the relative are unrelated to the candidate ($r_{ik} = 0$, $i$denoting the candidate), then the phenotype of the relative provides information only on the direct effect of the candidate, so that response in associative effect is entirely dependent on the genetic correlation between direct and associative effects. This is illustrated by the covariance between the total breeding value of the selection candidate and the phenotype of its relative, of which the component $\text{Cov}(A_{T,i}, \sum_{n-1} P_{S_k}) = 0$, so that $\text{Cov}(A_{T,i}, P_j) = r_{ij}[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]$ (Beware of a typo in this expression in [48]). In this case, accuracy is simply a scaled version of that with mass selection and unrelated group members,

$$\rho_{T,\text{rels}} = \frac{r_{\text{rels}}[\sigma^2_{A_D} + (n-1)\sigma_{A_{DS}}]}{\sigma_{A_T}\sigma_{\bar{P}_{\text{rels}}}}, \tag{33}$$

where r_{rels} is relatedness between the candidate and its relatives providing the information for selection. Hence, just as with mass selection, when using information recorded on sibs kept in groups with unrelated members, there is a risk of negative accuracy and thus negative response.

To capture the entire total breeding value of the selection candidates, relatedness between a candidate and the group mates of its relatives needs to be equal to relatedness between the candidate and its relatives, $r_{ik} = r_{ij}$, i denoting the candidate, j its relative, and k a group mate of j. In that case, $\text{Cov}(A_{T,i}, P_j) = \text{Cov}(A_{T,i}, A_{D,j} + \sum_{n-1} A_{S,k}) = r_{\text{rels}}\sigma^2_{A_T}$, showing that the phenotype of the relative captures the total breeding value of the candidate. This can be achieved by keeping relatives in family groups. For example, when selection is based on sib information, groups may be composed of full sibs of the candidate, so that $r_{ik} = r_{ij} = 0.5$. The following, therefore, describes the accuracy of selection based on relatives when they are kept in family groups.

The accuracy of selection based on the mean phenotypic value of relatives kept in family groups is an analogy of the classical expression for traits not affected by social interactions [48]. In the absence of social interactions, the accuracy of selection based on relatives is commonly expressed in terms of relatedness between the candidate and its relatives, r_{rels}, the square root of heritability, h, and the intraclass correlation t between the relatives (e.g., [63]),

$$\rho = \frac{r_{\text{rels}}h}{\sqrt{t + (1-t)/N}}, \tag{34}$$

where $t = r_w h^2$, being the product of mutual relatedness between the relatives, i.e., the within-family relatedness r_w, and heritability, and N is the number of records of relatives for each selection candidate. Note that there may be a difference between relatedness between the candidate and its relatives, r_{rels}, and mutual relatedness r_w within the group of relatives. For example, for half-sib progeny of the candidate, $r_{\text{rels}} = \frac{1}{2}$, whereas $r_w = \frac{1}{4}$. For full sibs of the candidate, $r_{\text{rels}} = r_w = \frac{1}{2}$, and for half sibs of the candidate, $r_{\text{rels}} = r_w = \frac{1}{4}$. When relatives are kept in family groups, with m groups per candidate each containing n members, yielding a total of mn records of relatives per candidate, the accuracy for socially affected traits equals,

$$\rho_{\text{rel}} = \frac{r_{\text{rels}}\eta}{\sqrt{\tau + (1-\tau)/mn}}, \tag{35a}$$

which is an analogy of Eq. 34 [48]. The Greek symbols in Eq. 35 are analogies of the "heritability" and the intraclass correlation;

$$\eta = \frac{\sigma_{\text{TBV}}}{\sigma_{\text{TPV}}} \tag{35b}$$

is an analogy of the square root of heritability, $h = \sigma_A/\sigma_P$, and

$$\tau = r_w\eta^2 \tag{35c}$$

is an analogy of the intraclass correlation between relatives $t = r_w h^2$. The η and τ account for interactions

among individuals, and, therefore, depend on the total breeding value (TBV) and on the total phenotypic value (TPV) contributed by an individual. The TPV is the phenotypic analogy of the TBV (Eq. 5). It is not the observed phenotype of the individual, but represents an individual's effect on all phenotypes in the population, which is the sum of its direct phenotypic effect and $n-1$ times its associative phenotypic effect, $P_{T,i} = P_{D,i} + (n-1)P_{S,i}$, so that,

$$\sigma^2_{P_T} = \sigma^2_{P_D} + 2(n-1)\sigma_{P_{DS}} + (n-1)^2\sigma^2_{P_S} \qquad (35d)$$

Thus, the TPV measures the total effect of an individual on performance of its group, the total breeding value is the heritable component of the TPV, and $\eta^2 = \sigma^2_{A_T}/\sigma^2_{P_T}$ is the proportion of the variance of the TPV which is heritable, analogous to the classical heritability. The intraclass correlation τ equals the correlation between TPVs of relatives, analogous to the classical intraclass correlation t, which equals the correlation between phenotypes of relatives for traits not affected by interactions [26]. In the absence of interactions, η reduces to h, τ reduces to t, and σ_{TBV} reduces to σ_A, so that Eq. 35a reduces to Eq. 34.

Hence, Eq. 35a shows that response to selection based on relatives kept in family groups can be obtained from the classical expression for response to selection based on relatives (Equation 34), when replacing heritability by $\sigma^2_{A_T}/\sigma^2_{P_T}$ and the intraclass correlation between relatives by $r_w\sigma^2_{A_T}/\sigma^2_{P_T}$. The key issue is that the sibs need to be kept in family groups. For example, when 16 half sibs are available and groups consist of 4 individuals, 4 groups of 4 individuals each should be used; the 16 half sibs should not be distributed over 16 groups each also containing 3 unrelated individuals.

Figure 5 illustrates the accuracy of selection based on relatives as a function of the number of groups of relatives per candidate. With many groups of relatives per candidate, $m \to \infty$, accuracy approaches

$$\max(\rho_{T,\text{rels}}) = \frac{r_{\text{rels}}}{\sqrt{r_w}}, \qquad (36)$$

which is 0.5 for half sib information, $\sqrt{0.5}$ for full sib information, and 1 for information on half-sib progeny

Socially Affected Traits, Inheritance and Genetic Improvement. Figure 5
Accuracy of selection methods. The accuracy is shown for individual selection when the animals in a group are either full sibs (♦) or unrelated (◇), for group selection with groups of full sibs (▲), and for selection based on relatives kept in family groups, as a function of the number of groups per candidate (m), where relatives can be either half sibs (■), full sibs (⁎) or half-sib progeny (●). (For $n = 4$; $\sigma^2_{P_D} = 1$; $\sigma^2_{P_S} = 0.33$; $h^2_D = 0.10$; $h^2_S = 0.10$; $r_A = r_E = 0$; Taken from Ellen et al. 2007)

of the candidate [26]. Those values are the same as for classical selection based on relatives. Hence, with selection based on phenotypes of relatives, limiting accuracies for socially affected traits are the same as those for classical traits. For example, it is possible to obtain an accuracy approaching unity by using information on a large number of half-sib progeny kept in groups consisting of half sibs.

Selection on Estimated Breeding Values (EBVs) In animal breeding practice, breeding values are usually estimated using the so-called BLUP-procedure (Best Linear Unbiased Prediction; [53]. In the traditional BLUP approach, phenotypes of individuals are analyzed using a mixed "animal model" containing fixed correction factors, such as herd, sex, or age of the individual, and a random genetic effect of the animal [27, 53, 64],

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Za} + \mathbf{e}, \qquad (37)$$

where **y** is a vector of phenotypes, **b** a vector of fixed correction factors with incidence matrix **X, a** a vector of random additive genetic effects ("breeding values") of individuals with incidence matrix **Z,** and **e** a vector of residuals (Note that elements of **y** in Eq. 37 correspond to P_i in Eq. 4.). In animal breeding, interest is in the vector of estimated breeding values, $\hat{\mathbf{a}}$. Estimates for fixed effects and breeding values are obtained from the so-called Mixed Model Equations (MME). When residuals are independent and identically distributed, the MME are [27, 53, 64]

$$\begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{Z} \\ \mathbf{Z}'\mathbf{X} & \mathbf{Z}'\mathbf{Z} + \alpha\mathbf{A}^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{b} \\ \mathbf{a} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\mathbf{y} \\ \mathbf{Z}'\mathbf{y} \end{bmatrix}, \tag{38a}$$

so that the estimates follow from

$$\begin{bmatrix} \hat{\mathbf{b}} \\ \hat{\mathbf{a}} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{X}'\mathbf{Z} \\ \mathbf{Z}'\mathbf{X} & \mathbf{Z}'\mathbf{Z} + \alpha\mathbf{A}^{-1} \end{bmatrix}^{-1} \begin{bmatrix} \mathbf{X}'\mathbf{y} \\ \mathbf{Z}'\mathbf{y} \end{bmatrix}, \tag{38b}$$

where **A** is a matrix of relatedness coefficients between all individuals in **a**, and $\alpha = \sigma_E^2/\sigma_A^2$. The use of BLUP requires knowledge of heritability of the trait to calculate the $\alpha = (1 - h^2)/h^2$. Further details and extensions are in [27, 64].

In contrast to selection index theory, BLUP is extremely flexible. It utilizes all available information, it allows correction for systematic non-genetic effects such as herd, sex or age, it allows for any degree of relatedness among individuals, any number of relatives, it provides also estimated breeding values for individuals without records, and it accounts for selection (under certain conditions).

Deterministic prediction of the accuracy of selection on BLUP-EBV is possible with selection index theory [65, 66], but is tedious, particularly when the model contains additional random effects such as maternal or associative effects. For this reason, consequences of selection on BLUP-EBV are often investigated using stochastic simulations. The following discusses the consequences of selection on BLUP-EBV when trait values are affected by associative effects, first when the mixed model ignores the associative effects, and afterward when accounting for associative effects.

BLUP Ignoring Associative Effects When only direct breeding values are modeled (i.e., when using Eq. 37), the consequences of selection on BLUP-EBV will depend critically on relatedness among group members [67]. When group members are unrelated, the EBV captures only the direct genetic effect of individuals, so that response in associative effects depends entirely on the genetic correlation between direct and associative effects. The accuracy derived from the MME, therefore, refers to the direct breeding value, not to the total breeding value. The actually achieved accuracy for the total breeding value is given by

$$\rho_{T,\mathrm{BLUP}}(r = 0) \approx \hat{\rho}_{\mathrm{MME}} \left[\frac{\sigma_{A_D}^2 + (n-1)\sigma_{A_{DS}}}{\sigma_{A_D}\sigma_{A_T}} \right] \tag{39}$$

The $\hat{\rho}_{\mathrm{MME}}$ is the ordinary accuracy of BLUP-EBV derived from the diagonal elements of the inverse of the coefficient matrix of the MME [64], and the term in square brackets is the correlation between the direct and total breeding value (Note that this result reduces to $\rho_{T,\mathrm{BLUP}}(r = 0) \approx \hat{\rho}_{\mathrm{MME}}$ when associative effects are absent). This result shows that BLUP selection with unrelated group member yields a negative accuracy when $\sigma_{A_D}^2 + (n-1)\sigma_{A_{DS}} < 0$, which is the same condition as for mass selection with unrelated group members (Table 2). When $\sigma_{A_D}^2 + (n-1)\sigma_{A_{DS}} < 0$, the correlated response in associative effects is negative and greater in absolute magnitude than the direct response, yielding a negative net response. Results of Muir [17] in cannibalistic quail illustrate that this is not merely a theoretical possibility, but may indeed occur in practice. (See section "Results of Social Selection Experiments" below.)

When groups are composed of families, the EBV of the traditional BLUP model implicitly captures the total breeding value of individuals, even though the associative component of trait values is not explicitly included in the model (Eq. 37; [67]). The reason is that the covariance between family members equals $r\sigma_{A_T}^2$, where $r = 0.5$ for full sibs and 0.25 for half sibs, when groups consist of family members (When groups are composed at random with respect to family, the covariance between sibs equals $r\sigma_{A_D}^2$). Consequently, the

accuracy of BLUP-EBV obtained from data containing groups of family members is approximately equal to the ordinary accuracy derived from the MME,

$$\rho_{T,\mathrm{BLUP,fam}} \approx \hat{\rho}_{\mathrm{MME}} \tag{40}$$

Moreover, the estimated additive genetic variance from an ordinary mixed model as in Eq. 37 will yield an estimate of $\sigma^2_{A_T}$ rather than $\sigma^2_{A_D}$. This occurs because the covariance between relatives equals $r\sigma^2_{A_T}$ rather than $r\sigma^2_{A_D}$ when groups consist of family members. Hence, the accuracy of BLUP-EBVs will always be positive when it is obtained from data consisting of family groups. This theoretical prediction agrees with results of Muir et al. [67] in quail, who found a negative response with BLUP selection and unrelated group members, but a positive response to BLUP selection when group members were related (referred to as Kin-BLUP in [67]).

BLUP Including Associative Effects Muir and coworkers [17, 22] extended the traditional mixed animal model to include Griffing's associative effects. In this model, the phenotype of each individual contains two separate components: a direct breeding value of the individual itself and the summed associative breeding values of its group mates,

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{e}, \tag{41}$$

where $\mathbf{y}$ is the usual vector of observations, $\mathbf{b}$ a vector of fixed effects with incidence matrix $\mathbf{X}$, $\mathbf{a}_D$ a vector of direct additive genetic effects with incidence matrix $\mathbf{Z}_D$ linking phenotypes of individuals to their own direct genetic effect, and $\mathbf{e}$ a vector of residuals. (Note that elements of $\mathbf{y}$ in Eq. 41 correspond to P_i in Eq. 4.) The $\mathbf{Z}_S\mathbf{a}_S$ represents the associative additive genetic effects, where $\mathbf{a}_S$ is a vector of associative effect, with incidence matrix $\mathbf{Z}_S$ linking phenotypes of individuals to the associative effects of their group mates. For example, for a population of 8 individuals kept in two groups of 4 individuals, individuals 1 through 4 in the first group and 5 through 8 in the second group, where individuals 2, 5, and 8 are female and the rest is male, a mixed model with a separate mean for both sexes and direct and associative effects for all records is

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \\ y_5 \\ y_6 \\ y_7 \\ y_8 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 0 \\ 1 & 0 \\ 0 & 1 \\ 1 & 0 \\ 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \mu_m \\ \mu_f \end{bmatrix}$$
$$+ \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} a_{D,1} \\ a_{D,2} \\ a_{D,3} \\ a_{D,4} \\ a_{D,5} \\ a_{D,6} \\ a_{D,7} \\ a_{D,8} \end{bmatrix}$$
$$+ \begin{bmatrix} 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} a_{S,1} \\ a_{S,2} \\ a_{S,3} \\ a_{S,4} \\ a_{S,5} \\ a_{S,6} \\ a_{S,7} \\ a_{S,8} \end{bmatrix}$$
$$+ \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \\ e_7 \\ e_8 \end{bmatrix}$$

The covariance structure of the random genetic terms is: $\mathrm{Var}\begin{bmatrix} \mathbf{a}_D \\ \mathbf{a}_S \end{bmatrix} = \mathbf{C} \otimes \mathbf{A}$, where $\mathbf{C} = \begin{bmatrix} \sigma^2_{A_D} & \sigma_{A_{DS}} \\ \sigma_{A_{DS}} & \sigma^2_{A_S} \end{bmatrix}$, $\mathbf{A}$ is a matrix of relatedness coefficients between individuals, and $\otimes$ denotes the Kronecker product of matrices. Thus, Eq. 41 is involves three genetic variance components, $\sigma^2_{A_D}$, $\sigma_{A_{DS}}$ and $\sigma^2_{A_S}$. (See section "Estimation of Genetic Parameters" below

for more details, such as the residual variance structure.)

The estimated breeding values for the direct and associative effects follow from the solution of the mixed model equations,

$$\begin{bmatrix} \hat{\mathbf{b}} \\ \hat{\mathbf{a}}_D \\ \hat{\mathbf{a}}_S \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\mathbf{R}^{-1}\mathbf{X} & \mathbf{X}'\mathbf{R}^{-1}\mathbf{Z}_D & \mathbf{X}'\mathbf{R}^{-1}\mathbf{Z}_S \\ \mathbf{Z}_D'\mathbf{R}^{-1}\mathbf{X} & \mathbf{Z}_D'\mathbf{R}^{-1}\mathbf{Z}_D + g^{11}\mathbf{A}^{-1} & \mathbf{Z}_D'\mathbf{R}^{-1}\mathbf{Z}_S + g^{12}\mathbf{A}^{-1} \\ \mathbf{Z}_S'\mathbf{R}^{-1}\mathbf{X} & \mathbf{Z}_S'\mathbf{R}^{-1}\mathbf{Z}_D + g^{21}\mathbf{A}^{-1} & \mathbf{Z}_S'\mathbf{R}^{-1}\mathbf{Z}_S + g^{22}\mathbf{A}^{-1} \end{bmatrix}^{-1} \times \begin{bmatrix} \mathbf{X}'\mathbf{R}^{-1}\mathbf{y} \\ \mathbf{Z}_D'\mathbf{R}^{-1}\mathbf{y} \\ \mathbf{Z}_S'\mathbf{R}^{-1}\mathbf{y} \end{bmatrix} \tag{42}$$

where $\mathbf{R}$ is the covariance matrix of the residuals, $\mathbf{R} = \mathrm{Var}(\mathbf{e})$, and the g^{ij} denote elements of the inverse of the genetic covariance matrix, $\begin{bmatrix} g^{11} & g^{12} \\ g^{21} & g^{22} \end{bmatrix} = \begin{bmatrix} \sigma^2_{A_D} & \sigma_{A_{DS}} \\ \sigma_{A_{DS}} & \sigma^2_{A_S} \end{bmatrix}^{-1}$. The elements of $\mathbf{R}$ are given in the section on "Estimation of Genetic Parameters" below.

When fitting Eq. 41, fixed effects and potential additional random effects must be chosen carefully because not only an individual's direct effect but also its associative effect may be affected by fixed and random factors. Hence, in addition to the ordinary fixed effects, which refer to effects on the individual producing the record, one may need to fit fixed effects for its group mates. For example, when groups consist of mixed breeds, one may fit a fixed associative effect for the breed of each group mate. When associative breed effects are omitted, they may inflate the estimated associative effects and their variance. Similarly, when groups consist of mixed sexes, one may fit a fixed associative effect for the sex of each group mate. Moreover, when common-litter effects play a role, one may fit a random common-litter associative effect [41]. An example is given in the section on "Estimation of Genetic Parameters" below.

Deterministic prediction of the accuracy of selection on BLUB-EBV obtained from Model 41 is very tedious. In principle, selection index theory can be used to derive that accuracy, using the pseudo-BLUP selection index methodology suggested by [66]. However, for a population consisting of full and half sib families, a pseudo-BLUP selection index for a single trait contains 24 distinct sources of information. Hence, the variance matrix of the index contains 24^2 elements. Thus the use of stochastic simulation is more practical.

Some insight in the factors determining accuracy of BLUP selection can be obtained from a simplified index. The selection index of Muir et al. [67] shows that relatedness between group members may have greater impact on accuracy than extension of the mixed model to account for associative effects. They compared Kin-BLUP, in which the mixed model contained direct effects only (Eq. 37) and group members were related, to C-BLUP, in which the mixed model contained both direct and associative effects (Eq. 41), but group members were unrelated. The accuracy of Kin_BLUP exceeded that of C_BLUP, and the correlation of the true associative BV with the EBV of Kin_BLUP was greater than that with the associative EBV of C_BLUP. Hence, though Kin_BLUP does not explicitly account for associative effects, it can have greater accuracy for associative effects than C_BLUP. This result agrees with the empirical observations of Muir et al. [67] who observed greater response with Kin-BLUP than with C-BLUP in cannibalistic quail. Kin_BLUP picks up associative effects because they are hidden in the own performance and FS-performance when group members are related.

In conclusion, both empirical and theoretical results indicate that relatedness within groups is the key factor for response to selection; the use of C_BLUP does not make relatedness superfluous. C_BLUP, however, will always outperform Kin_BLUP when applied to the same breeding structure because it explicitly models the associative effects. When both methods are applied to data with full-sib groups, for example, C_BLUP will outperform Kin_BLUP [67].

A Special Case: Maternal Genetic Effects Maternal genetic effects are a common case of social interactions among individuals, where the mother affects the trait values of her offspring. Maternally affected traits usually depend on both the genes for maternal effect in the mother and genes for direct effect in the offspring [23, 27, 68, 69]. Preweaning growth rate and survival of piglets, for example, will depend on maternal milk yield and behavior of the sow, but also on the direct effect of the piglets for growth rate. Other examples are calving ease in dairy cattle [70], and preweaning survival in sheep [71].

Maternal effects should not be confused with the genes for direct effect that the offspring inherits from its mother, but refers to the effect of the mother on her offspring that arises through the environment, for example, due to maternal care. Hence, direct and maternal effects are genetically distinct traits. For growth rate in piglets, for example, genes for direct effect will relate to juvenile growth rate, whereas genes for maternal effect may relate to milk yield or behavior of sows.

Maternal effects may be modeled as [68, 69]

$$P_i = A_{D,i} + E_{D,i} + A_{M,j} + E_{M,j}, \tag{43}$$

where i is the offspring, j the mother, P_i is the phenotype of the offspring, A_D and A_M the direct and maternal breeding values, and E_D and E_M the non-heritable direct and maternal effects, respectively. From Eq. 43, response to selection equals the sum of the changes in mean direct and mean maternal breeding value [68, 69],

$$R = \Delta\bar{A}_D + \bar{\Delta}A_M, \tag{44}$$

Based on Eq. 44, Eaglen and Bijma [49] defined a total breeding value for maternally affected traits, being the sum of an individual's breeding values for direct and maternal effect,

$$A_T = A_{D,i} + A_{M,i}, \tag{45}$$

so that response to selection equals $R = \Delta\bar{A}_T$. In contrast to the phenotypic value, the total breeding value includes the individual's own breeding value for maternal effect, rather than that of its mother. This is because an individual transmits its own genes for maternal effects to its offspring, not those of its mother. The total heritable variance that can be used to generate response to selection in maternally affected traits equals the variance in total breeding values among individuals,

$$\sigma^2_{A_T} = \sigma^2_{A_D} + 2\sigma_{A_{DM}} + \sigma^2_{A_M} \tag{46}$$

From Eq. 17, response to selection equals [49]

$$R = \imath\rho_M\sigma_{A_T}, \tag{47}$$

where ρ_M is the accuracy of selection for maternally affected traits, which is the correlation between the selection criterion and the total breeding value of an individual.

A number of studies have referred to a "total heritability" [72, 73], citing Willham [69],

$$h^2_r = \frac{\sigma^2_{A_D} + 1\frac{1}{2}\sigma_{A_{DM}} + \frac{1}{2}\sigma^2_{A_M}}{\sigma^2_P} \tag{48}$$

Willham [23, 69] referred to h^2_r as the "fraction of the selection differential realized if selection were on P_x" (P_x being the offspring phenotype). Hence, h^2_r represents the realized heritability for mass selection, $h^2_r = R/S$, the ratio of response over the selection differential, rather than the ratio of heritable variance over phenotypic variance [68]. Thus response to mass selection can be predicted as $R = h^2_r S$. Equation 47 yields the same result for mass selection, but applies to any selection strategy.

Maternal genetic effects can be estimated using mixed models that include both a direct and maternal genetic effect [64]. Issues related to the estimation of maternal genetic effects are discussed in [23, 64, 74–78].

Results of Social Selection Experiments Only a few social selection experiments have been applied in livestock. Muir [19] selected laying hens, housed in half-sib groups, based on total egg production per group. Hence, this experiment combined group selection with relatedness. In six generations, mortality decreased from 67% to 8%. Most of the response occurred within the first few generations of selection. Eggs per hen housed increased from 91 to 237 eggs, mainly as a result of increased survival. In the seventh generation, the group selected and control lines were compared to the commercial line from which the group selected line was derived [20, 79, 80]. In single-bird cages, egg production was significantly greater for the commercial line. In 12-bird cages, however, the reverse was seen. The most remarkable difference was for mortality at 58 weeks of age, which was 89% for the commercial line, 20% for the group selected line and 54% for the control. These results confirm the theoretical expectation that group selection with related group members yields large response to selection when associative effects are important.

The changes in mortality were accompanied by changes in behavior, stress physiology, and

immunology [81, 82].Under conditions of social stress, birds from the low mortality population were more hesitant to attack other birds, showed less feather pecking, had a lower H/L ratio and had lower dopamine and corticosterone blood concentrations, indicating lower stress levels [83, 84]. Cheng and Muir [82] suggested that these changes in birds from the low mortality population may reflect a greater ability to cope with novel environments and to have a greater resistance to stressors than birds from the high mortality population.

Muir and coworkers [17, 22, 67] presented results of 25 cycles of selection for body weight in quail housed in groups of 16 birds. Three selection programs were compared. First, selection on conventional animal model BLUP EBV considering direct effects only (AM_BLUP, Eq. 37). Second, selection on estimated total breeding values derived from a mixed model, including both direct and associative effects (C_BLUP, Eq. 41). Group members were unrelated in those selection programs. The third selection program used groups consisting of half-sibs families, and selection on conventional animal model BLUP EBV considering direct effects only (Kin_BLUP). Results showed that the AM_BLUP program decreased body weight and increased mortality, whereas the Kin_BLUP program increased body weight and decreased mortality. The C_BLUP program was intermediate. Those results agree with expectations based on the theory presented above.

At Wageningen University, Ellen and coworkers initiated a selection experiment in laying hens, combining individual selection for egg number and group selection for low mortality in non-beak-trimmed kin-groups, based on the method of [48]. Selection candidates were housed individually, allowing recording of individual egg number. Non-beak-trimmed full sibs of these selection candidates were housed in family groups in which mortality was recorded. Selection was for a combination of egg number and mortality. Rodenburg et al. [85, 86] and Bolhuis et al. [87] investigated the behavioral and physiological consequences of this selection program in the second generation. Animals of the selected line were less fearful and less sensitive to stressors in a range of behavioral tests. Consistent results were found both in young chicks [87] and in adult birds [88] in two environments (cages and floor pens).

A number of group selection experiments have been performed in laboratory species, particularly in flour beetles (*Tribolium castaneum*). Wade [58, 59] was the first to demonstrate the power of group selection experimentally. Goodnight [89] reviewed 12 group selection experiments. Without exception, all group selection experiments showed a significant response to selection both in animals, plants, and microbial communities. Similar results have been found in bacteria [90]. Again, those results demonstrate that selection between groups and use of related group members increases response to selection in traits affected by social interactions, which agrees with theoretical expectations (see above).

Estimation of Genetic Parameters

Statistical Methodology

Some of the selection methods described above can be applied without knowledge of the genetic parameters, such as mass and group selection. Without knowledge of the genetic parameters, however, it is unclear whether associative effects are present and whether those selection strategies are needed and/or efficient. Moreover, most applied breeding programs make use of Best Linear Unbiased Prediction [53] for estimating breeding values, e.g., to correct for systematic environmental effects, which requires knowledge of the genetic parameters. Knowledge of the genetic parameters is also needed to quantify the expected response to selection, which may be required to make decisions on investment in breeding programs. Moreover, there is a wider biological interest in the heritable components affecting individual trait values and responses to selection, both in agriculture and in other fields of biology such as evolutionary genetics [30, 62]. Thus there is a need to estimate the genetic parameters for socially affected traits, which are the additive genetic variances of direct genetic effects, $\sigma^2_{A_D}$, the additive genetic variances of associative effects, $\sigma^2_{A_S}$, and the additive genetic covariance of direct and associative effects, $\sigma_{A_{DS}}$. This section addresses the estimation of those parameters, starting with a review of existing results.

Empirical Estimates of the Associative Variance Table 3 summarizes estimates of direct and associative heritabilities. Brichette et al. [37] were the first to publish estimates of the associative genetic variance. They analyzed growth in mussel cultures and found strongly significant direct and associative effects. Their model is somewhat different from the mixed models discussed in this chapter, and estimates may not be directly comparable. In each group, they tested a single focal family against a mixed reference set containing members of all families. In this design, the effect of the focal family on the mean phenotype of the reference group represents the associative effect of that family. Hence, in this setup, the associative effect is defined for a set of family members, rather than for a single individual, and the factors $(n-1)$ and $(n-1)^2$ in the total genetic variance do not apply (Eq. 7). Brichette et al. [37] obtained direct heritabilities of 0.104 and 0.232 for length measures, and 0.097 and 0.234 for area measures. Corresponding estimates for associative heritability were 0.010 and 0.087 for length and 0.220 and 0.082 for area. Direct-associative genetic correlations were negative, averaging −0.2. These results suggest that $\sigma^2_{A_t}/\sigma^2_P \approx 0.24$, and that associative effect contributed ∼1/3 of heritable variance in growth of mussel cultures.

$\hat{h}^2_D = \hat{\sigma}^2_{A_D}/\hat{\sigma}^2_P$, $\hat{h}^2_S = \hat{\sigma}^2_{A_S}/\hat{\sigma}^2_P$, $\hat{T}^2 = \hat{\sigma}^2_{A_T}/\hat{\sigma}^2_P$, $\hat{r}_{A_{DS}} = \hat{\sigma}_{A_{DS}}/(\sigma_{A_D}\sigma_{A_D})$, see Eqs. 4–9 for further information.
[a][34], first 28 days of growth period, no evidence for associative effects found in other periods.
[b][35], significance levels not reported.
[c][24], individuals were not beak-trimmed.
[d][36], individuals were not beak-trimmed.
[e][37].
[f]The h^2_S is defined somewhat different here, see text.
[g][15].
[h][38], for d= 1.
[i][39], model 2.
[j]H [40], model 2, significance levels tested against model 6.
[k][41], model 4.
[l] [17], non-genetic associative effects not accounted for, thus $\hat{\sigma}^2_{A_S}$ and $\hat{T}^2$may be inflated; significance levels not reported. NR: not reported. n.s. not significantly different from zero.

Later studies focused primarily on laying hens and pigs. Particularly in pigs and beef cattle, it has proven difficult to reliably estimate the associative genetic variance. Often the estimates suggested a considerable contribution of associative effects to total heritable variance ($T^2 >> h^2_D$), but the estimated associative genetic variance was nevertheless not significantly different from zero (Table 3). This occurred particularly when group sizes were relatively large, so that the number of groups was fairly small [25]. These observations agree with theoretical predictions, which indicate that the number of groups is the major determinant of statistical power, and that designs with small groups are often superior ([32]; see section on "Power and Optimum Designs" below). Hence, in large groups, even small values of the associative heritability can make a major contribution to total heritable variation (Eq. 7), but this contribution is difficult to estimate accurately, as reflected by the large standard errors of $\hat{\sigma}^2_{A_T}$. Estimates in laying hens, which come from data containing groups of four individuals, have been more accurate [24, 36].

Several studies have shown that the estimated associative genetic variance is very sensitive to the choice of the statistical model. Models not accounting for non-genetic associative effects, i.e., models that fit neither environmental associative effects nor pen effects or correlated residuals, generally yielded strongly inflated estimates [34, 40, 91, 92]. Hence, the choice of the statistical model requires careful consideration. To properly estimate the genetic variance components, additional fixed and random associative effects may be required to account for other sources of variation, such as litter environment or group size (see below).

QTL: There appears to be only a single QTL-study involving associative effects. Biscarini et al. [93] performed an association study to map direct and associative QTL for feather damage across nine different genetic lines of laying hens. A total population of 662 hens were genotyped for 1022 SNPs. Eleven significant SNPs were detected for direct effect and 81 for associative effect. From the significant associative SNPs, six were located at the sex chromosome. The SNPs identified suggest a relationship between

behavior and immunology, and a role of the serotonergic system in feather pecking.

Mixed Models Muir and coworkers [17, 22] extended the traditional mixed animal model to include Griffing's associative effects (See Eq. 41 above). The following describes an extension of their model, taking the basic model as a starting point. In the basic model (Eq. 3), observed trait values are the sum of direct and associative effects, $P_i = P_{D,i} + \sum_{j=1}^{n-1} P_{S,j}$. The full direct and associative effects are not solely genetic, but may depend also on fixed effects, random genetic effects, and other random effects such as permanent or litter effects,

$$P_{D,i} = \text{fixed}_D + A_{D,i} + E_{D_P,i} + E_{D_C,i} + E_{D,i} \quad (49a)$$

$$P_{S,i} = \text{fixed}_S + A_{S,i} + E_{S_P,i} + E_{S_C,i} + E_{S,i}, \quad (49b)$$

where subscripts P and C indicate permanent and common-litter effects, respectively. (Note that Eqs. 49a and b are not exhaustive; they may be extended with, e.g., maternal genetic effects.) Just as in classical mixed models, omission of associative permanent effects or associative common-litter effects may lead to overestimation of $\sigma^2_{A_S}$. In pigs, for example, two full sibs may develop similar social skills because they experienced the same litter environment. In the fattening period, this similarity in social skills will create a covariance between the pen mates of both full sibs. When not accounted for, this covariance will largely be attributed to the associative genetic variance because the mixed model implies that $\text{Cov}(\bar{P}_{\text{pen mates}(FS1)}, \bar{P}_{\text{pen mates}(FS2)}) = \frac{1}{2}\sigma^2_{A_S}$ when associative litter effects are not included. A similar reasoning applies to permanent effects. For example, when an individual has been member of two distinct groups, the covariance between the phenotypes of two group mates, one taken from each group, equals $\sigma^2_{A_S} + \sigma^2_{E_S}$. When permanent associative effects are omitted from the mixed model, this covariance will be fully attributed to associative genetic effects, leading to overestimation of $\sigma^2_{A_S}$.

In general, therefore, the mixed model for socially affected traits is given by

$$\mathbf{y} = \{\mathbf{X}_D\mathbf{b}_D + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_{D_P}\mathbf{e}_{D_P} + \mathbf{Z}_{D_C}\mathbf{e}_{D_C} + \cdots + \mathbf{e}_D\} + \{\mathbf{X}_S\mathbf{b}_S + \mathbf{Z}_S\mathbf{a}_S + \mathbf{Z}_{S_P}\mathbf{e}_{S_P} + \mathbf{Z}_{S_C}\mathbf{e}_{S_C} + \cdots + \mathbf{e}_S\} \quad (50)$$

where subscripts D and S indicate direct and associative effects, P and C indicate permanent and common-litter effects, $\mathbf{X}$ and $\mathbf{Z}$ denote incidence matrices, and $\mathbf{e}$ the residual. Whether or not a specific model component needs to be included will depend on the data structure. Direct and associative fixed effects may often be fully confounded, so that fitting a single effect is sufficient. For example, group members will usually be in the same herd at the same time. Hence, the direct and associative herd-year effects will be fully confounded, so that fitting a single herd-year effect suffices. In some cases, therefore, the simplest model, $\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{e}$, may be appropriate. (But see the section on "Non-Genetic Associative Effects" below.)

In other cases, however, additional fixed or random associative effects may be required. Consider, for example, a pen of four beef cows, the first individual being a Hereford, and individuals two through four being Charolais. In this situation, fitting both a direct and an associative fixed breed-effect may be appropriate,

$$\mathbf{y} = \mathbf{X}_D\mathbf{b}_D + \mathbf{X}_S\mathbf{b}_S + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{e}$$

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} H_D \\ C_D \end{bmatrix} + \begin{bmatrix} 0 & 3 \\ 1 & 2 \\ 1 & 2 \\ 1 & 2 \end{bmatrix} \begin{bmatrix} H_S \\ C_S \end{bmatrix} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{e}$$

where H_D and C_D are the fixed direct breed effect of Hereford and Charolais, respectively, and H_S and C_S are the fixed associative breed effect of Hereford and Charolais, respectively. The record of individual 1, for example, contains three fixed Charolais associative effects, because its three pen mates are all of the Charolais breed. When associative breed effects are omitted, they may partly end up in the estimated associative genetic variance. Moreover, when groups consist of mixed sexes, fitting a fixed associative effect for sex of the group mates may be appropriate.

As a second example, consider social interactions in fattening pigs. Because litter-mates may develop

similar social skills, fitting a common-litter associative effect is of interest in this case [15]. Consider a pen of 8 individuals originating from three distinct litters; individuals 1 through 3 are born in litter 1, individual 4 is born in litter 2, and individuals 5 through 8 are born in the third litter. The mixed model for this pen is

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{Z}_{C_D}\mathbf{e}_{C_D} + \mathbf{Z}_{C_S}\mathbf{e}_{C_S} + \mathbf{e} \tag{51}$$

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \\ y_5 \\ y_6 \\ y_7 \\ y_8 \end{bmatrix} = \mathbf{Xb} + \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} a_{D,1} \\ a_{D,2} \\ a_{D,3} \\ a_{D,4} \\ a_{D,5} \\ a_{D,6} \\ a_{D,7} \\ a_{D,8} \end{bmatrix}$$

$$+ \begin{bmatrix} 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 0 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} a_{S,1} \\ a_{S,2} \\ a_{S,3} \\ a_{S,4} \\ a_{S,5} \\ a_{S,6} \\ a_{S,7} \\ a_{S,8} \end{bmatrix}$$

$$+ \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} e_{C_D,1} \\ e_{C_D,2} \\ e_{C_D,3} \end{bmatrix}$$

$$+ \begin{bmatrix} 2 & 1 & 4 \\ 2 & 1 & 4 \\ 2 & 1 & 4 \\ 3 & 0 & 4 \\ 3 & 1 & 3 \\ 3 & 1 & 3 \\ 3 & 1 & 3 \\ 3 & 1 & 3 \end{bmatrix} \begin{bmatrix} e_{C_S,1} \\ e_{C_S,2} \\ e_{C_S,3} \end{bmatrix} + \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \\ e_5 \\ e_6 \\ e_7 \\ e_8 \end{bmatrix}$$

The $\mathbf{Z}_S$ links the record of each individual to the associative genetic effect of its group mates, whereas $\mathbf{Z}_{C_S}$ links the record of each individual to the litter of its group mates. Hence, with groups of 8 individuals, each row of both $\mathbf{Z}_S$ and $\mathbf{Z}_{C_S}$ has a sum of 7, because each individual has 7 group mates. For this model, the variance structures for genetic effects is $\mathrm{Var}\begin{bmatrix} \mathbf{a}_D \\ \mathbf{a}_S \end{bmatrix} = \mathbf{G} \otimes \mathbf{A}$, where $\mathbf{G} = \begin{bmatrix} \sigma^2_{A_D} & \sigma_{A_{DS}} \\ \sigma_{A_{DS}} & \sigma^2_{A_S} \end{bmatrix}$, $\mathbf{A}$ is the usual numerator relationship matrix [27], and $\otimes$ denotes the Kronecker product of matrices. The variance structure of the common-litter effects is $\mathrm{Var}\begin{bmatrix} \mathbf{e}_{C_D} \\ \mathbf{e}_{C_S} \end{bmatrix} = \mathbf{C} \otimes \mathbf{I}$, where $\mathbf{C} = \begin{bmatrix} \sigma^2_{E_{C_D}} & \sigma(E_{C_D}, E_{C_S}) \\ \sigma(E_{C_D}, E_{C_S}) & \sigma^2_{E_{C_S}} \end{bmatrix}$, and $\mathbf{I}$ is an identity matrix of dimension equal to the number of litters. The $\sigma^2_{E_{C_D}}$ is the variance of the (usual) direct litter effects, $\sigma^2_{E_{C_S}}$ the variance of the associative litter effects, and $\sigma(E_{C_D}, E_{C_S})$ the covariance between the direct and associative effect of a litter. Hence, Eq. 51 involves the estimation of six variance components and the residual variance. (See below for the variance structure of the residual). Canario et al. [38] showed that an associative common-litter effect may be required to prevent overestimation of the associative genetic variance in fattening pigs.

Non-Genetic Associative Effects In both above examples, the direct residual effect of the focal individual and the associative residual effects of its group mates have been summarized into a single residual, $e_i = E_{D,i} + \sum_{j=1}^{n-1} E_{S,j}$. This is because the non-genetic parameters $\sigma^2_{E_D}$, $\sigma_{E_{DS}}$ and $\sigma^2_{E_S}$ are not uniquely identifiable when group size is constant [39, 40, 92]. Hence, a model including both E_S and a (direct) residual is overspecified. Nevertheless, non-genetic associative effects have consequences for the variance structure of the residuals. First, the residual variance becomes dependent on group size [39, 92],

$$\sigma^2_e = \sigma^2_{E_D} + (n-1)\,\sigma^2_{E_S}, \tag{52}$$

Hence, when group size varies in the data, it may be appropriate to fit a separate residual variance for each group size. Second, the residuals of group mates become correlated [39, 92],

$$\mathrm{Cov}(e_i, e_j) = 2\sigma_{E_{DS}} + (n-2)\sigma^2_{E_S}, \tag{53}$$

where i and j are group mates. Equations 52 and 53 illustrate that the non-genetic variance components are non-identifiable because there are only two observable (co)variances in the data, but three unknowns. In other words, there is an infinite number of combinations of $\sigma^2_{E_D}$, $\sigma_{E_{DS}}$ and $\sigma^2_{E_S}$ that yield the same values of σ^2_e and $\mathrm{Cov}(e_i, e_j)$ [15, 39, 92]. (This becomes different when group sizes vary; see below).

Equation 53 shows that the residual covariance may take negative values, particularly when groups are small. In that case, it may be required to allow for correlated residuals within group in the mixed model, using [92] $\mathrm{Var}(\mathbf{e}) = \mathbf{R}\sigma^2_e$, with

$$R_{ii} = 1, \tag{54}$$

$R_{ij} = \rho_e$ when i and j are group mates, and $R_{ij} = 0$ when i and j are in different groups.

This results in a block-diagonal structure for the correlation matrix of residuals, $\mathbf{R}$. For two groups of four individuals, for example, the correlation matrix of residuals equals

$$\mathbf{R} = \begin{bmatrix} 1 & \rho_e & \rho_e & \rho_e & 0 & 0 & 0 & 0 \\ \rho_e & 1 & \rho_e & \rho_e & 0 & 0 & 0 & 0 \\ \rho_e & \rho_e & 1 & \rho_e & 0 & 0 & 0 & 0 \\ \rho_e & \rho_e & \rho_e & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & \rho_e & \rho_e & \rho_e \\ 0 & 0 & 0 & 0 & \rho_e & 1 & \rho_e & \rho_e \\ 0 & 0 & 0 & 0 & \rho_e & \rho_e & 1 & \rho_e \\ 0 & 0 & 0 & 0 & \rho_e & \rho_e & \rho_e & 1 \end{bmatrix}$$

The correlation between residuals of group mates equals $\rho_e = \left[2\sigma_{E_{DS}} + (n-2)\sigma^2_{E_S}\right] / \left[\sigma^2_{E_D} + (n-1)\sigma^2_{E_S}\right]$. This structure can be fitted in ASREML using the CORU statement in the description of the R-structure [94].

When groups are reasonably large, the residual correlation is likely to be positive because the $(n-2)\sigma^2_{E_S}$ becomes the dominant term in Eq. 53. In that case, one can account for residual correlations by adding a random group effect to the model and fitting independent residuals [15, 34, 39]. Fitting a random group effect is computationally easier than fitting correlated residuals and is therefore preferable when the correlation between residuals of group mates is positive. This leads to the model

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S + \mathbf{Z}_g\mathbf{g} + \mathbf{e}, \tag{55}$$

where $\mathbf{g}$ is a vector of random group effects, with incidence matrix $\mathbf{Z}_g$ linking phenotypes of individuals to their group, $\mathrm{Var}(\mathbf{g}) = \mathbf{I}\sigma^2_g$, $\mathrm{Var}(\mathbf{e}) = \mathbf{I}\sigma^2_e$, $\mathbf{I}$ denoting an identity matrix, σ^2_g the between-group non-genetic variance and σ^2_e the residual variance. With Eq. 55,

$$\sigma^2_g = 2\sigma_{E_{DS}} + (n-2)\sigma^2_{E_S}, \textit{ and} \tag{56a}$$

$$\sigma^2_e = \sigma^2_{E_D} - 2\sigma_{E_{DS}} + \sigma^2_{E_S} \tag{56b}$$

Note that, in contrast to Eq. 41, the residual variance of Eq. 55 is independent of group size, whereas the between-group variance depends on group size. Hence, when group size varies in the data, it may be appropriate to fit a different group variance for each group size. (But see the section "Accounting for Variation in Group Size" below.)

Ignoring non-genetic associative effects, e.g., by omitting a group effect and fitting a simple residual, may inflate the estimated genetic variance components by as much as 200–300% [39, 40, 92]. In this case, the covariance between trait values of group mates, which equals $2\sigma_{P_{DS}} + (n-2)\sigma^2_{P_S}$, is attributed entirely to the genetic components because the model implies that $\mathrm{Cov}_{\text{group mates}} = 2\sigma_{A_{DS}} + (n-2)\sigma^2_{A_S}$.

Accounting for Variation in Group Size The above has ignored variation in group size within a population, which will be very common in practice. When group sizes vary in the population, merely fitting a fixed effect for group size may not be sufficient because variance components may also differ between group sizes. For example, interactions among individuals may be less intense in large groups, meaning that the associative genetic variance decreases with group size.

When the underlying parameters, $\sigma^2_{A_D}$, $\sigma_{A_{DS}}$, $\sigma^2_{A_S}$, $\sigma^2_{E_D}$,$\sigma_{E_{DS}}$ and $\sigma^2_{E_S}$ are assumed to remain constant, variation in group size requires only modifying the variance structure of the non-genetic part of the model. In the genetic part of the model (Eq. 51), $\mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_S\mathbf{a}_S$, variation in group size is automatically accounted for in $\mathbf{Z}_S$. Consequences for the non-genetic part of the model will depend on the model. When fitting a model with correlated residuals, both the residual variance and the residual within-group correlation will vary among group sizes (Eqs. 52–54). When fitting a model with random group effects, the group

variance will be heterogeneous among group sizes while the residual variance is homogeneous (56 and Eqs. 57). Hence, when the underlying variance components are assumed constant, a model including a random group effect is more easily adapted to account for varying group size.

However, assuming that the underlying parameters remain constant with varying group size is a strong a priori assumption. In many cases, associative effects may become smaller in larger groups because they are distributed over more group mates, a phenomenon known as "dilution" [25, 42, 43]. In principle, one could estimate separate genetic parameters for each group size. However, this would be a waste of information, and require large data sets for each group size. A simpler solution is to scale the magnitude of associative effects by a factor depending on the inverse of the number of group mates (Eq. 11),

$$A_{S,i,n} = \left(\frac{\bar{n}-1}{n-1}\right)^d A_{S,i,\bar{n}},$$

where $A_{S,i,n}$ represents the associative effect of individual i when expressed in a group of n members, $A_{S,i,\bar{n}}$ the associative effect when expressed in a group of the average size, and d the degree of dilution. Further details on dilution of associative effects are summarized above in the section "The Effect of Group Size on Heritable Variance".

The degree of dilution can be estimated from data containing variation in group size by using a mixed model with Restricted Maximum Likelihood and evaluating the likelihood for different fixed values of d [25, 38]. Estimates of A_S, $\sigma^2_{A_S}$ and $\sigma_{A_{DS}}$ referring to the average group size may be obtained from the following mixed model [38, 43],

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_{S(d)}\mathbf{a}_{S,\bar{n}} + \mathbf{Z}_g\mathbf{g} + \mathbf{e}, \tag{57}$$

where $\mathbf{y}$ is the vector of observations, $\mathbf{Xb}$ are the usual fixed effects, $\mathbf{Z}_D\mathbf{a}_D$ are the direct genetic effects, $\mathbf{Z}_g\mathbf{g}$ are random group-effects, and $\mathbf{e}$ is a vector of residuals. The $\mathbf{a}_{S,\bar{n}}$ is a vector of associative effects referring to the average group size, and $\mathbf{Z}_{S(d)}$ is the incidence matrix for associative effects, which depends on the degree of dilution. Elements of $\mathbf{Z}_{S(d)}$ are

$$\mathbf{Z}_{S(d)}(i,j) = \left(\frac{\bar{n}-1}{n_i-1}\right)^d \text{ when } j \text{ is a group member of } i,$$
$$\mathbf{Z}_{S(d)}(i,j) = 0 \text{ otherwise,} \tag{58}$$

where $\bar{n}$ denotes the average group size, and n_i the size of the group of individual i. This model yields estimates of genetic parameters and breeding values referring to the average group size because the $[(\bar{n}-1)/(n_i-1)]^d = 1$ when $n_i = \bar{n}$.

When non-genetic associative effects depend on group size in the same manner, also the group and residual variance for the model in Eq. 57 will depend on group size [43],

$$\sigma^2_{g,n} = 2\left(\frac{\bar{n}-1}{n-1}\right)^d \sigma_{E_{DS},\bar{n}} + (n-2)\left(\frac{\bar{n}-1}{n-1}\right)^{2d} \sigma^2_{E_S,\bar{n}} \tag{59a}$$

$$\sigma^2_{e,n} = \sigma^2_{E_D} - 2\left(\frac{\bar{n}-1}{n-1}\right)^d \sigma_{E_{DS},\bar{n}} + \left(\frac{\bar{n}-1}{n-1}\right)^{2d} \sigma^2_{E_S,\bar{n}} \tag{59b}$$

Hence, to obtain unbiased estimates of the genetic parameters and d, it may be required to fit a separate group and residual variance for each group size. An alternative solution is to explicitly model E_S. When group size is constant, the non-genetic parameters cannot be estimated, and a model including both E_S and a residual is overspecified (See below Eq. 53). When group size varies, however, $\sigma^2_{E_D}$, $\sigma_{E_{DS}}$ and $\sigma^2_{E_S}$ may be identifiable (unless $d = 1$), and it may be possible to fit the model

$$\mathbf{y} = \mathbf{Xb} + \mathbf{Z}_D\mathbf{a}_D + \mathbf{Z}_{S(d)}\mathbf{a}_{S,\bar{n}} + \mathbf{Z}_{S(d)}\mathbf{e}_{S,\bar{n}} + \mathbf{e},$$

with $\mathrm{Var}\begin{bmatrix}\mathbf{e}_{S,\bar{n}}\\ \mathbf{e}\end{bmatrix} = \mathbf{E}\otimes\mathbf{I}$, where $\mathbf{E} = \begin{bmatrix}\sigma^2_{E_{S,\bar{n}}} & \sigma(E_D, E_{S,\bar{n}})\\ \sigma(E_D, E_{S,\bar{n}}) & \sigma^2_{E_D}\end{bmatrix}$.

However, it may not be possible to implement the nonzero $\mathrm{Cov}(\mathbf{e}_{S,\bar{n}}, \mathbf{e})$ of this model in standard software.

Canario et al. [38] present estimates for the degree of dilution of both associative genetic effects and associative common-litter effects in fattening pigs, with group sizes varying from 5 through 15 individuals. Their results suggest that both effects are fully diluted with group size ($\hat{d} = 1$). Their results also indicate that

the estimate of the associative variance may depend on whether or not the analysis accounts for dilution.

Hadfield and Wilson [42] presented an alternative approach to account for the relationship between associative effects and group size. They fit an additional associative genetic effect that is proportional to the inverse of the number of group mates. Bijma [43] compares their model to Eq. 57, and concludes that it has greater flexibility, but is also less tractable.

Identifiability of the Associative Genetic Variance Not all data structures are equally suited for estimating the genetic variance of associative effects. A particularly critical aspect is group composition. When groups are composed of equally related individuals, for example, full or half-sib families, then direct and associative effects are fully confounded and cannot be estimated [34, 92, 95]. Also the use of specific distributions of families over groups may cause non-identifiability of the associative genetic variance [92]. Genetic parameters are identifiable when groups are composed at random with respect to family, but the standard error of $\hat{\sigma}^2_{A_S}$ may be large. Groups composed of members of two distinct families yield more precise estimates of $\sigma^2_{A_S}$ (See section "Statistical Power and Optimum Designs" below).

Moreover, the associative genetic variance is not identifiable when a fixed group-effect is fitted [96]. When fitting group as a random effect, however, $\sigma^2_{A_S}$ is identifiable and simulations with normally distributed group effects indicate that estimates are unbiased [92]. Nevertheless, the non-identifiability of $\sigma^2_{A_S}$ when using fixed group effects indicates that the information for estimating $\sigma^2_{A_S}$ is closely linked to variation in the group means, suggesting that estimates may be sensitive to the distribution of group effects. The importance of the group agrees with the observation of Bijma [97], who found that number of groups, rather than number of individuals, is the main determinant of the standard error of $\hat{\sigma}^2_{A_S}$. Cantet and Cappa [96] present methods to investigate whether variance components are identifiable from a particular data set.

Statistical Power and Optimum Designs

Standard Errors of Estimated Variance Components Optimization of experimental designs and evaluation of the power of experiments aiming to estimate genetic parameters for socially affected traits requires knowledge of the factors determining the standard errors (SE) of estimated parameters. Accurate prediction equations for those SEs are available for balanced designs containing N_f families with n_f members each, yielding a total of $N_t = N_f\, n_f$ individuals in the experiment [97]. Two group compositions have been investigated; groups composed at random with respect to family, and groups composed of two families. In the latter design, each group is composed of members of two distinct families, each family contributing ½n individuals. This design leads to a block structure (Table 4), where each of the families within a block is combined with each of the other families in that same block, each combination occurring precisely once.

For both designs, the SEs of estimated genetic variances follows from

$$\mathrm{SE}(\hat{\sigma}^2_A) \approx \frac{1}{r}\sqrt{\frac{2}{N_f-1}\left[\sigma^4_f + \frac{2\sigma^2_f\sigma^2_e}{m} + \frac{\sigma^4_e}{m(m-1)}\right]}, \tag{60}$$

where N_f is the number of families, m the effective number of records per family, σ^2_f the between-family variance, and σ^2_e the residual variance,

$$\sigma^2_e = \sigma^2_z - \sigma^2_f, \tag{61}$$

Socially Affected Traits, Inheritance and Genetic Improvement. Table 4 Example of the design with groups composed of two distinct families

	Family B				
Fam. A	2	3	4	5	6
1	2/2	2/2	2/2	2/2	2/2
2		2/2	2/2	2/2	2/2
3			2/2	2/2	2/2
4				2/2	2/2
5					2/2

Group size equals n= 4. Each group consists of members of two distinct families, each family contributing two individuals. Family size equals n_f = 10, so that each family can be combined with 10/(½ × 4) = 5 other families. Thus a block consists of six families, each being combined with each of the five other families in that block. Hence, there are 5*6/2 = 15 groups per block, 15*4 = 60 individuals per block, and $N_t/60$ blocks, N_t denoting the total number of individuals in the experiment.

where σ_z^2 is the variance of an "effective record" [97]. Equations 60 and 61 allow prediction of $\mathrm{SE}(\hat{\sigma}^2_{A_D})$, $\mathrm{SE}(\hat{\sigma}^2_{A_S})$ and $\mathrm{SE}(\hat{\sigma}^2_{A_T})$. Application of those Equations requires knowledge of m, σ_z^2 and σ_f^2, which depend on the parameter and experimental design of interest, and are given in Table 5 for schemes with groups composed at random, and in Table 6 for schemes with groups composed of two distinct families.

The SE of the estimated genetic covariance, $\mathrm{SE}(\hat{\sigma}_{A_{DS}})$ follows from

$$\mathrm{SE}(\hat{\sigma}_{A_{DS}}) = \sqrt{\frac{\mathrm{SE}(\hat{\sigma}^2_{A_D})\ \mathrm{SE}(\hat{\sigma}^2_{A_S})}{2} + \frac{\sigma^2_{A_{DS}}}{N_f - 1}}, \quad (62)$$

where $\mathrm{SE}(\hat{\sigma}^2_{A_D})$ and $\mathrm{SE}(\hat{\sigma}^2_{A_S})$ follow from Eq. 60.

The SE of the ratio of total heritable variance over phenotypic variance follows from

$$\mathrm{SE}(\hat{T}^2) \approx \frac{\mathrm{SE}(\hat{\sigma}^2_{A_T})}{\sigma^2_P}, \quad (63)$$

where $\mathrm{SE}(\hat{\sigma}^2_{A_T})$ follows from Eq. 60. An accurate prediction equation for the SE of the estimated genetic correlation between direct and associative effects is available only for cases where the true value of this correlation is near zero. Designs with two families per group yield lower $\mathrm{SE}(\hat{\sigma}^2_{A_S})$ than schemes with groups composed at random with respect to family, except when group size equals two individuals, in which case both designs are nearly equivalent [97].

Socially Affected Traits, Inheritance and Genetic Improvement. Table 5 Components of SEs[a] with random group composition

Parameter	Expression	
All VC	$m = n_f$	
	$\sigma^2_P = \sigma^2_{P_D} + (n-1)\,\sigma^2_{P_S}$	
	$\mathrm{Cov}_\omega = 2\sigma_{P_{DS}} + (n-2)\,\sigma^2_{P_S}$	
$\hat{\sigma}^2_{A_D}$	$\sigma^2_z = \sigma^2_P$	$\sigma^2_f = r\sigma^2_{A_D}$
$\hat{\sigma}^2_{A_S}$	$\sigma^2_z = \frac{\sigma^2_P + (n-2)\mathrm{Cov}_\omega}{n-1}$	$\sigma^2_f = r\sigma^2_{A_S}$
$\hat{\sigma}^2_{A_T}$	$\sigma^2_z = n\left[\sigma^2_P + (n-1)\mathrm{Cov}_\omega\right]$	$\sigma^2_f = r\sigma^2_{A_T}$

[a]SEs for the estimated genetic variance of interest follow from substituting σ^2_z and σ^2_f for that parameter into Eq. 60.

Socially Affected Traits, Inheritance and Genetic Improvement. Table 6 Components of SEs[a] with group composed of two distinct families (See Table 4)

Parameter	Expression	
All VC	$m = 2n_f/n$	
	$\sigma^2_P = \sigma^2_{P_D} + (n-1)\sigma^2_{P_S} + 2r\left(\frac{1}{2}n - 1\right)\left[\sigma_{A_{DS}} + \left(\frac{1}{2}n - 1\right)\sigma^2_{A_S}\right]$	
	$\mathrm{Cov}_{\omega,\mathrm{fam}} = 2\sigma_{P_{DS}} + (n-2)\sigma^2_{P_S} + r\left[\sigma^2_{A_D} + 2(\frac{1}{2}n - 2)\sigma_{A_{DS}} + (\frac{1}{2}n^2 - 2n + 3)\sigma^2_{A_S}\right]$	
	$\mathrm{Cov}_{\omega,\mathrm{nonfam}} = 2\sigma_{P_{DS}} + (n-2)\sigma^2_{P_S} + 2r(\frac{1}{2}n - 1)\left[\sigma_{A_{DS}} + (\frac{1}{2}n - 1)\sigma^2_{A_S}\right]$	
	$\mathrm{Var}(\bar{P}_{\mathrm{fam}}) = \dfrac{\sigma^2_P + (\frac{1}{2}n - 1)\mathrm{Cov}_{\omega,\mathrm{fam}}}{\frac{1}{2}n}$	
$\hat{\sigma}^2_{A_D}$	$\sigma^2_z = (1 + \varphi^2)\,\mathrm{Var}(\bar{P}_{\mathrm{fam}}) - 2\varphi\,\mathrm{Cov}_{\omega,\mathrm{nonfam}}\varphi = \dfrac{\frac{1}{2}n - 1}{\frac{1}{2}n}$	$\sigma^2_f = r\sigma^2_{A_D}$
$\hat{\sigma}^2_{A_S}$	$\sigma^2_z = \frac{4\,\mathrm{Var}(\bar{P}_{\mathrm{fam}})}{n^2}$	$\sigma^2_f = r\sigma^2_{A_S}$
$\hat{\sigma}^2_{A_T}$	$\sigma^2_z = \frac{4}{n}\left[\sigma^2_P + (\frac{1}{2}n - 1)\mathrm{Cov}_{\omega,\mathrm{fam}} + \frac{1}{2}n\mathrm{Cov}_{\omega,\mathrm{nonfam}}\right]$	$\sigma^2_f = r\sigma^2_{A_T}$

[a] SEs for the estimated genetic variance of interest follow from substituting σ^2_z and σ^2_f for that parameter into Eq. 60.

For designs with group composed at random, the optimum family size for estimating a genetic variance is

$$n_{f\,\mathrm{opt},\sigma^2,\mathrm{random}} \approx \sigma_z^2/\sigma_f^2 \tag{64a}$$

For designs with group composed of two families, the optimum family size for estimating a genetic variance is

$$n_{f\,\mathrm{opt},\sigma^2,2\mathrm{fam}} \approx \frac{1}{2}\,n\,\sigma_z^2/\sigma_f^2 \tag{64b}$$

These expressions can be applied for the genetic variance of interest by using the appropriate σ_z^2 and σ_f^2 from Tables 5 or 6. Results of Eqs. 64a and b show that optimum family size for estimating $\sigma_{A_S}^2$ may be very large when group are composed at random and may differ considerably from optimum family size for estimating $\sigma_{A_D}^2$. When groups are composed of two families, optimum family size for estimating $\sigma_{A_S}^2$ is smaller, and more similar to that for $\sigma_{A_D}^2$. Thus the scheme with two families per group may be a good compromise to estimate both the direct and associative genetic variance [97].

Expressions for optimum group sizes for estimating $\sigma_{A_S}^2$ are not available. Numerically obtained results in [97] indicate that optimum group sizes are small ($\leq$3–4) in most cases. Optimum group sizes are large only for designs with two families per group, and only when the number of groups, rather than the number of individuals, is the limiting factor in the experiment. An R-package named SE.IGE is available, which calculates SEs and optimum family and group sizes, and can be downloaded from the repository of R-packages, CRAN, at http://cran.r-project.org/package=SE.IGE, following the usual method to install R-packages.

Future Directions

This chapter has summarized the quantitative genetic theory of traits affected by social interactions among individuals and reviewed the existing empirical evidence for such effects. The theoretical framework is now well developed, both in the field of artificial selection and in evolutionary biology [18, 56, 57]. The theory of genetic variance, inheritance, and response to selection has been developed [17, 31], and statistical methodology to estimate associative variance components has become available [17, 22, 25, 39, 92, 98]. Selection experiments and data analysis provide convincing evidence of substantial associative effects on survival time in cannibalistic laying hens and quail [17, 19, 21, 24, 36, 67, 93]. The evidence is less strong for other livestock species, such as pigs and beef cattle, where some studies have found large effects [15], but others none or only small effects [25, 95]. Further research is required on those species. Associative effects appear to be very relevant for aquaculture populations as well (see below), but estimates of the associative genetic variance are almost completely lacking at present.

Genetic improvement of associative effects has the potential to contribute significantly to animal welfare because a significant proportion of welfare issues is related to mutual behaviors [99]. Well-known examples are feather pecking and cannibalism in laying hens [100], and fighting after mixing and tail biting in pigs [14]. In the past, genetic improvement of behaviors has been hampered by the cost and labor involved in routine collection of behavioral data. As a consequence, breeding for improved behavior is rare in livestock genetic improvement. The use of associative-effect models offers the potential to solve this problem because they estimate the associative effect from the resulting phenotype without the need to observe the causative behavior. Biscarini et al. [93], for example, identified 81 QTL for associative effect on plumage condition, without observing feather pecking behavior.

Not all welfare problems are related to behavioral interactions among animals. Welfare is also threatened by metabolic stress related to high efficiency of production [4]. Results in quail [17] and in Medaka [101, 102] suggest that a genetic reduction of agonistic behaviors may produce strains that waste less resources on competitive behaviors. This suggests that genetic improvement of associative effects may have the potential to increase the efficiency of production without increasing metabolic stress. Whether this phenomenon is widespread awaits further empirical testing.

Though the statistical methodology to estimate associative variance components is available, application is practice has many pitfalls, particularly in pigs, and careful model comparison is required to assess the stability of the estimates [15, 34, 39, 91]. The omission of random group effects from the statistical model, for example, may yield a strongly overestimated associative

genetic variance. Interpretation of early results has been hampered by the lack of a proper theoretical framework to judge the relevance of the estimated associative genetic variance, which is often very small compared to phenotypic variance, but can nevertheless contribute substantially to heritable variance. The definition of a total heritable variance facilitates interpreting the relevance of associative effects for livestock genetic improvement [31]. If current estimates of the associative genetic variance in pigs and laying hens reflect the true parameters, then selection for associative effects can increase rates of genetic improvement considerably. Particularly in pigs and aquaculture, there is a need for validation by means of selection experiments.

A challenging problem is the improvement of associative effects when populations are kept in large groups, which is increasingly the case. When groups are large, the number of groups is usually small, which hampers the estimation of genetic parameters. Investigation of optimum designs to estimate genetic parameters shows that the number of groups, rather than the number of individuals, is the primary determinant of statistical power [97]. Moreover, in large groups, the intensity of the interactions is probably less, as found in pigs [38], which reduces the accuracy of estimated genetic parameters and breeding values. This issue requires further investigation.

Optimum designs for maximizing response to selection suggest a trade-off between improvement of associative effects and rates of inbreeding. The key factor to increase response to selection is the use of related group members (see above). However, such designs will probably increase the correlation between EBVs of relatives, which in turn increases rates of inbreeding when selection is based on EBVs. Rates of inbreeding can be restricted by using flexible selection algorithms, such as optimum contribution selection [103–105]. Hence, high rates of inbreeding can be avoided, but this may be at the expense of response to selection. This issue has not yet been investigated; it probably becomes less relevant when breeders start using genomic selection (see below and in [106]).

Particularly interesting is the relationship between competition and variability. Breeders have long been interested in increasing uniformity. However, though animal breeders have successfully increased the average performance of livestock, genetic improvement of uniformity has proven difficult. In the classical model, where $P = A + E$, opportunities for genetic changes in variability are very limited [107]. At best, breeders can achieve $\sigma_A^2 \approx 0$, which reduces phenotypic standard deviation by only ~16% when heritability equals 0.3. There is, however, increasing evidence that the environmental variance is under direct genetic control [e.g., 108, 109], and theoretical models for inherited variability have been developed [110–112]. Results suggest a substantial genetic coefficient of variation in the environmental variance, but also a difficulty to obtain reliable estimated breeding values for environmental variance [112].

The mechanisms underlying such inherited variability are largely unknown at present. In aquaculture, competition for feed is believed to inflate size variation among individuals. In carp, for example, Moav and Wohlfarth [16] found greater variability in ponds of mixed genetic strains than in ponds of a single genetic strain. Results in Medaka [101, 102] suggest that behavioral consequences of selection for growth depend on whether or not there is competition for feed in the selection environment. To limit size variation among individuals, regular grading of fish is common practice in aquaculture. Because group selection has the potential to reduce competition among individuals (see above), it seems to be a promising tool for reduction of variability in aquaculture. At present, however, there appear to be no studies on the consequences of group selection for variability in aquaculture. Current models of associative effects (see above) cannot explain a relationship between competition and variability because the phenotypic variance is independent of the average social breeding value. Hence, extension of current models is required to theoretically link variability and competition. The link between competition and variability may, however, largely be an empirical, rather than theoretical, issue.

At present, the use of genome wide marker information is rapidly increasing in livestock genetic improvement. A method know as Genomic Selection [6], which estimates effects of markers covering the entire genome, has become a routine tool in dairy cattle breeding and will soon be adapted by breeders of other livestock species. Genomic selection extends readily to socially affected traits, which seems particularly useful

for crossbreeding schemes. A comparison of estimated genetic parameters for direct and associative effects for survival in cannibalistic laying hens shows large differences between purebred parental lines [24] and their crossbred offspring [36]. The genetic correlation between direct and social effects appears to be strongly negative in crossbreds, while around zero in purebreds. Moreover, estimated parameters differ between reciprocal crosses. Those results indicate considerable "GxE-interaction" between purebreds and crossbreds. Genomic selection based on phenotypes recorded on crossbreds can be used to predict breeding values of nucleus individuals for direct and social effects referring to crossbred performance. Hence, combining genomic selection with associative-effect models seems promising to reduce mortality due to cannibalism in commercial crossbred herds.

Glossary

Chalcopyrite compounds These compounds originate from the mineral $CuFeS_2$ and are composed of elements with valence states I–III–VI_2. Due to ordering of the different cations, the unit cell is a doubled zinc blende unit cell.

Defects Disorders of the crystal lattice either intrinsically (vacancies, interstitials, antisites) or by extrinsic impurities. Photovoltaic quality of the material depends on the concentration of defects.

Grain boundaries Interfaces between different grains.

Heterojunctions In contrast to pn junctions formed by doping a homogeneous semiconductor, heterojunctions use to two different semiconductors.

High efficiency Present high-efficiency PV modules reach efficiencies 15% to over 20% in production.

Polycrystalline thin films The films consist of single grain with a size in the order of the thickness of the film or smaller. Typical grain sizes are in the 0.1–5 μm range.

Thin-film solar cells Solar cells that are produced by technologies that allow deposition of materials on very large areas. Depending on the absorber material, thicknesses are in the range of 0.1–20 μm.

Definition of Subject

Developments in photovoltaics technologies aim for solutions that allow manufacturing of efficient photovoltaic modules at low cost. The chalcopyrite-type compounds $Cu(In,Ga)(S,Se)_2$ (CIGS) or (CIS) are semiconductors which could significantly contribute as thin-film materials to the future share of photovoltaics in the supply of electrical power. In a long-lasting

process of understanding the specific properties, CIGS became one of the most attractive materials for efficient thin-film photovoltaic modules. The remarkable attention received by CIGS as a future material for thin-film solar cells results from the specific properties of this fascinating semiconductor:

- Lab cell efficiencies beyond 20%
- Very high flexibility for manufacturing
- Free choice of substrates (glass or flexible foils)

The high-efficiency potential makes it one of the most important materials for thin-film photovoltaic technologies.

Introduction

The history of CIGS began in the early 1950s when the ternary compound $CuInSe_2$ was first synthesized and semiconducting properties were identified by Hahn et al. [1]. At that time, photovoltaics was still limited to Se-based photodetector applications until the first Si- and CdS-based solar cells reached notable conversion efficiencies in the mid-1950s. In parallel to the development of crystalline, Si solar cells, the first chalcogenide-based thin-film solar cells, in particular, Cu_2S–CdS, were considered as promising technology approaching efficiencies of 10% in the late 1970s. Further development of this technology was hampered by stability problems of the ionic conductor Cu_2S under photovoltaic operation. Adding indium to the binary copper chalcogenide compound created an intrinsically stable compound. The publication of a 12% efficient photovoltaic device based on a $CuInSe_2$ single crystalline in 1974 by Shay and Wagner [2] draws first attention to this material. In the first attempts to produce thin-film solar cells, the $CuInSe_2$ absorber layers were prepared by evaporation of the ternary compound $CuInSe_2$ from a single source. Kazmerski et al. [3] were able to demonstrate the first thin-film solar cells. Later, coevaporation of the single elements yielded devices with efficiencies approaching 10% [4]. A first review of the chances and obstacles of CIS-based solar cells was given by Kazmerski [5] in 1983. The concerns regarding the performance of this kind of solar cells have been largely overcome:

- Device efficiency can compete with polycrystalline Si solar cells.
- Stability has been proven in outdoor operation and accelerated testing.

The Cu-chalcopyrite compound $CuInSe_2$ and its alloys $Cu(In,Ga)(Se,S)_2$ provide the absorber material for the to date most efficient thin-film solar cells. The high optical absorption coefficient of the chalcopyrite compounds allow absorber layers with a thickness <1 μm well suited for thin flm solar cells.

A high-power conversion efficiency of more than 20% obtained with an alloy $Cu(In,Ga)Se_2$ (with a Ga/(Ga+In)-ratio $\sim$0.3) reaches the performance of conventional wafer-based polycrystalline silicon solar cell technology. Even though the first results of the development were very promising, it took a decade until the first commercial CIGS modules were produced. Only after some important modifications of the growth and composition of the absorber film the material reached its full potential. The addition of Ga stabilized p-type conductivity and increased the bandgap. The key for control of film growth and free-carrier concentration is the use of sodium-containing glass or the deliberate addition of Na to the growth process. These developments were mostly empirical and sometimes serendipitous. In the meantime, advanced techniques for microanalysis and calculation of defects by density functional theory led to a deeper understanding of the properties of these complex materials. The involvement of more research teams worldwide has improved basic understanding as a prerequisite for reproducible manufacturing processes.

The generic CIGS device in Fig. 1 is based upon a so-called substrate structure. In contrary to the superstrate design of most CdTe and thin-film silicon-based modules, the CIGS solar cell structure can be built on opaque substrates. The present design of a CIGS cell is the result of a historic development based upon empirical optimization. Improved knowledge about the material and devices now allows systematic developments. Even though there is no significant difference between the structure of devices in laboratory dimensions and in large-area modules, the difference between maximum large-area module efficiencies of about 14% and record laboratory efficiency exceeding 20% [6] is remarkable.

Multinary Chalcopyrite Compounds as Photovoltaic Materials

From the beginning of the development, CIS turned out to be a very efficient PV material. However, the complexity of the material impeded a systematic development. Hence, early progress and success were driven by empirical development connected to lucky circumstances such as the success of chemically deposited CdS buffer layers in connection with ZnO transparent contacts. The tolerance of the material at moderate efficiency levels was long-time misleading with respect to the necessary control of deposition processes. An important discovery was the impact of Na on the quality of absorber films. The controlled introduction of Na during growth leads to real breakthrough in device performance.

The ternary compound $CuInSe_2$ has an 80-mV lower bandgap than silicon and therefore below the optimum for efficient conversion of the solar radiation. Besides the technologically advantageous features including the outstanding radiation hardness of $CuInSe_2$ and its alloys [7], the Cu-chalcopyrites attract also considerable scientific interest because of their unusual defect physics: for example, the ability to form electronically inactive defect complexes explains the great tolerance of these materials to deviation from stoichiometry and to foreign impurities.

The success of the chalcopyrite compounds, in particular, $CuIn(Ga)Se_2$, results from their very beneficial material properties. Besides the high optical absorption, electronic properties are very well suited for solar cells. Synthesis of thin films at moderate temperatures on cheap substrates complies with the requirements for large-scale production.

Possibilities for the design of efficient photovoltaic thin-film devices are significantly extended by alloys of multinary chalcogenide compounds. Since the bandgap can easily be increased by adding Ga and S, the $Cu(In_{1-x}Gax)(Se_{1-y}S_y)_2$ alloy system provides wide design options for processing and properties for the development of high-efficiency solar cells with high-open-circuit-voltage solar cells as the bandgap energy E_g of $CuInSe_2$ increases upon alloying with Ga. The range of bandgaps which are covered by the Cu-chalcopyrite is displayed in Fig. 2. Typical CIGS cells have a bandgap of 1.15–1.2 eV as highlighted in the figure.

Structure and Defects

The chalcopyrite semiconductors belong to the adamantine structure derived from the diamond lattice. There, lattice elements are tetrahedrally coordinated like in all adamantine (diamond-like) semiconductors. The tetragonal chalcopyrite structure of, for example, $CuInSe_2$ is derived from the cubic zinc blende structure

Solar Cells, Chalcopyrite-Based Thin Film. Figure 3 Structure of zinc blende (*cubic*) and chalcopyrite (*tetragonal*) compounds

of II–VI materials like ZnSe by occupying the Zn sites alternately with Cu and In atoms. In the chalcopyrite structure, each I (Cu) or III (In) atom has four bonds to the VI atom (Se). In turn, each Se atom has two bonds to Cu and two to In. The crystal structure of the I–III–VI_2 compounds of CIS is shown in Fig. 3.

With the chalcogen sublattice being unchanged (with the exception that positions of the anions are slightly distorted), the cation lattice sites are occupied by different group I and group III elements. Because the strengths of the I–VI and III–VI bonds are different, the ratio of the lattice constants c/a is not exactly 2, i.e., it varies from 2.01 in $CuInSe_2$ to 1.96 in $CuGaSe_2$. Due to the multitude of elements and compounds involved in the formation of $Cu(In_{1-x}Gax)(Se_{1-y}Sy)_2$ films, the resulting defect structure is quite complex.

Phase Diagram The phase diagrams have been extensively investigated by Goedecke et al. [8]. These investigations had a special focus on temperatures and compositions relevant for the preparation of thin films. On the Cu-rich side of the $CuInSe_2$ single-phase region of the phase diagram, Cu_2Se segregates as a secondary phase. In thin films, Cu_2Se can be easily removed by dissolving in potassium cyanide (KCN) solution leaving behind a $CuInSe_2$ or $Cu(In,Ga)Se_2$ film which is slightly Cu poor. Films prepared with an originally Cu-rich composition exhibit good electronic quality (e.g., from photoluminescence) [9, 10]. However, solar cells with absorber films grown in such a way are far less efficient than those with a slightly Cu-deficient absorber.

The related compound $CuInS_2$ - gained some attention as absorber material for thin-film solar cells [11]. In this case, growth processes rely on the Cu-rich growth of the films in connection with subsequently removing excess CuS by dissolving in KCN solution. Cu-poor growth immediately leads to deterioration of the film quality by the segregation of spinel type phase $CuIn_5Se_8$.

The ternary phase diagram can be reduced to a simpler pseudobinary phase diagram along the tie line between Cu_2Se and In_2Se_3. By combining these two compounds, $CuInSe_2$ is formed:

$$x\,(Cu_2Se) + (1 - x)\,In_2Se_3 \qquad 0 < x < 1.$$

There are three different phases which have been found to be adjacent to the chalcopyrite: α-phase ($CuInSe_2$), the β-phase ($CuIn_3Se_5$), and the δ-phase (the high-temperature sphalerite phase, $Cu_{2-y}Se$). An interesting point is that the phases adjacent to the α-phase have a similar structure. The β-phase is actually a defect chalcopyrite phase built by ordered arrays of defect pairs (Cu vacancies V_{Cu} and In–Cu antisites In_{Cu}). Similarly, $Cu_{2-y}Se$ can be derived from the chalcopyrite by using Cu–In antisites Cu_{In} and Cu interstitials Cu_i. Disordering the cation (Cu, In), sublattice causes the transition to the sphalerite phase and leads back to the zinc blende structure. Neutron or anomalous X-ray diffraction allows detailed insight in the defect structure because site occupancy is reflected by variation of diffraction peak intensities [12].

The existence range of the chalcopyrite phase in pure $CuInSe_2$ at room temperature extends from a Cu content of 24–24.5% on the quasi-binary Cu_2Se–In_2Se_3 tie line [8]. Thus, the existence range of single-phase $CuInSe_2$ is small and does even not include the stoichiometric composition of 25% Cu. The Cu content of absorbers for efficient thin-film solar cells typically varies between 22 and 24 at.% Cu. At the growth temperature of 500–550°C, this region

lies within the single-phase region of the α-phase. However, at room temperature, it lies outside this region of the equilibrium phase diagram in [8]. Hence, there is a tendency for phase separation in $CuInSe_2$ after deposition. Fortunately, it turns out that partial replacement of In with Ga, as well as the use of Na-containing substrates, considerably widens the single-phase region in terms of ratios (In + Ga)/(In + Ga + Cu) >0.5 [15]. Thus, the studies of the phase diagram, especially in connection with the addition of Ga and Na, explain the substantial improvements actually achieved in recent years by adding Na to the growth process either from Na-containing substrates or from Na-containing precursor layers, as well as by using $Cu(In,Ga)Se_2$ alloys. First, in these films, about 20–30% of the In is replaced by Ga, and second, these films grow on Na-containing glass and, consequently, contain around 0.1 atom % Na that diffuses out of the glass during deposition. The incorporation of both Ga and Na inhibits the ordering of the defect complexes and, hence, the formation of secondary Cu-poor phases in the bulk of the thin film [13].

Further important properties for the collection of photocurrent in solar cells are charge-carrier mobilities. Electron mobilities in single crystals reach more than 900 cm^2/Vs [14]. In connection with lifetimes of several ns, the electron diffusion length is in the order of a few μm. Diffusion length and minority carrier lifetimes depend very much on the preparation conditions of the thin films. With an absorption length for the solar radiation with an energy above the bandgap below 1 μm in combination with a sufficient diffusion length of photogenerated carriers, CIGS-based solar cells could reach very high efficiencies with a thickness of less than a μm.

Defects The semiconductor compound $CuIn(Ga)Se_2$ is extremely tolerant to defects (i.e., deviations from stoichiometry, crystallographic imperfections, and grain boundaries due to fortunate circumstances) [15, 16] (note: this is only true for $CuIn(Ga)Se_2$ and, in part, for $CuInS_2$):

- Secondary phases have commensurate structures, i.e., phase segregations do not cause severe distortion during growth.
- Cu vacancies are not electrically active defects but just reduce the density of states in the valence band. Therefore, deviations from stoichiometry, in particular, Cu/In+Ga ratios, form neutral defect complexes.
- Other relevant defects like Cu_{In} are energetically positioned in the conduction band.

The complex defect structure of ternary or multinary semiconductor makes control of electronic properties by extrinsic doping mostly impossible. On the one hand, simply considering valence states of dopants is not leading to reliable results, because foreign elements could occupy any lattice site and act as donor or acceptor. On the other hand, a high level of impurities can be tolerated, in particular, at moderate efficiencies (<15%).

There is much room for device design and the need for working around limitations by processing the material in a way where defects are minimized. It is important to note that device optimization is not possible by simple engineering based on textbook solutions but requires understanding of the complex material science of a system with numerous components. Reconstruction of surfaces leads to the formation of defect structures that are not electrically active in terms of surface recombination. These very lucky circumstances make surface and grain boundaries self-passivating [15]. The tendency of the compound to stabilize in a state with a minimum of electrically active defects allows for flexibility in film preparation. If the film is slightly Cu poor and the processing ends with a high-temperature step (>400–600°C), reasonable device efficiencies can be reached.

The role of defects in the ternary compound $CuInSe_2$, and even more in $Cu(In,Ga)Se_2$, is of special importance because of the large number of possible intrinsic defects [17] and the role of deep recombination centers in the performance of the solar cells [18]. The defect physics in $Cu(In,Ga)Se_2$ explains:

- Doping of $Cu(In,Ga)Se_2$ has to rely on native defects
- Extrinsic doping by foreign impurities is not possible
- The tolerance of electrical properties to large off-stoichiometries

– The electrically neutral nature of the structural defects

Efficiency limitations might arise only from minor potential fluctuations due to local modulation of energy bands. It is obvious that the understanding of these effects significantly contributes to the explanation of the photovoltaic performance of this material. Intrinsic defects control doping of $CuInSe_2$. Samples are *p*-type conductive if the material is grown Cu poor and under high Se vapor pressure, whereas Cu-rich material with Se deficiency tends to be *n*-type [19, 20]. The Se vacancy V_{Se} is considered to be the dominant donor in *n*-type material (and also the compensating donor in *p*-type material), and the Cu vacancy V_{Cu}, the dominant acceptor in Cu-poor *p*-type material.

In contrast to the binary compounds where small deviations from stoichiometry cause drastic changes of the electronic properties, the ternary compounds, in particular, $CuInSe_2$, are much more tolerant, at least with respect to the composition of the group 1 or group III metals. The Cu content of device-quality $CuInSe_2$ or $Cu(In,Ga)Se_2$ absorbers varies typically between 22at.% and 24 at.% Cu. Even though these films strongly deviate from the 25:25:50% composition, they maintain favorable optoelectronic properties which make them well suited for photovoltaic devices. A nonstoichiometry of 1% would correspond to a defect concentration of roughly 10^{21} cm^{-3}. This concentration is far beyond the net doping concentration in films of about 10^{17} cm^{-3} in the photovoltaic active part of a solar cell.

The concentration of defects resulting from off-stoichiometry of the group I and III metals has to be compatible with the good electronic quality that is required for a photovoltaic device. Deviations of the valence stoichiometry, i.e., the proper Se/metals ratio according to the pseudobinary Cu_2Se–In_2Se_3 tie line, cause significant changes of the electronic properties. If the material is grown under Se saturation, the Se content in the film is self-adjusting, i.e., excess Se reevaporates and the selenium vacancy concentration adjusts according to the thermodynamic equilibrium.

There are two possibilities that could lead to a material with good electronic properties at high stoichiometry deviations: either the nonstoichiometry is accommodated in a secondary phase that is not harmful to the photovoltaic performance or the off-stoichiometry-related defects are electronically inactive. In $CuInSe_2$, both mechanisms are realized. The two point defects which are related to an overall Cu-poor composition are the Cu vacancy V_{Cu} (a shallow acceptor) and the In–Cu antisite In_{Cu} (a deep double donor). According to first-principle calculations, these two defects form a defect complex ($2V_{Cu}$, In_{Cu}) which is electronically neutral and has no energy levels within the energy gap of $CuInSe_2$ [21]. Therefore, these complexes are not electronically active defects. Ordered arrays of the ($2V_{Cu}$, In_{Cu}) complex can be considered as the building blocks of a series of Cu–In–Se compounds like $CuIn_3Se_5$ and $CuIn_5Se_8$ [22], i.e., the secondary phases that delimit the single-phase region of $CuInSe_2$ toward the Cu-poor side. Due to the lower Cu concentration, these compounds have a lower valence band energy and, hence, a wider bandgap. Segregations of these phases occur in thin films and Cu-poor single crystals [23]. For the metal-related defects in $CuInSe_2$ and $CuGaSe_2$, the defect formation energies for some intrinsic defects are low and depend on the chemical potential of the components (i.e., by the composition of the compound) as well as by the electrochemical potential of the electrons (i.e., the energetic position of Fermi level). For V_{Cu} in Cu-poor and stoichiometric material, a negative formation energy implies the spontaneous formation of those defects if the Fermi level changes. Low (but positive) formation energies are also found for the Cu-on-In antisite Cu_{In} in Cu-rich material (this defect is a shallow acceptor which could be responsible for the p-type conductivity of Cu-rich, non-Se-deficient $CuInSe_2$). The dependence of the defect formation energies on the electron Fermi level could explain the strong tendency of $CuInSe_2$ to self-compensation and the difficulties of achieving extrinsic doping. The work of [22] provides a theoretical basis for the calculation of defect formation energies and defect transition energies, which exhibit good agreement with experimentally obtained data. The formation energies of some defect complexes such as the combination of antisite defects with vacancies ($2V_{Cu}$, In_{Cu}), (Cu_{In}, In_{Cu}) and interstitials ($2Cu_i$, Cu_{In}) are even lower than those of corresponding isolated defects [23].

As the ($2V_{Cu}$, In_{Cu}) complex is most likely to occur in In-rich material, it can accommodate a large amount of excess In (or likewise Cu deficiency). Since ($2V_{cu}$, In_{Cu}) does not exhibit defect levels within the forbidden gap, off-stoichiometry does not significantly influence the electrical performance of the material. Furthermore, ordered arrays of this complex can be thought as the building blocks of the In-rich Cu–In–Se compounds such as $CuIn_3Se_5$ and $CuIn_5Se_8$ [12]. Defects and related clusters have been verified by structural analysis with Rietveld refinement of neutron and anomalous X-ray scattering spectra [12].

Surface Properties The surface of In-rich films as measured by photoelectron spectroscopy (XPS) exhibits the 1–3–5 composition of the $Cu(In,Ga)_3Se_5$ defect phase [24, 25], i.e., the surface is always more Cu poor than the bulk of the material. The surface reconstruction is accompanied by Cu depletion of the uppermost atomic layers of the CIGS surface. Most likely, the Cu-poor surface of these thin films is not the consequence of the segregation of a secondary bulk phase but rather the result from the accumulation of Cu-deficiency-related defects and defect complexes. The precise properties of this surface defect layer are not yet known and still under discussion. However, it is of major importance that the bandgap at the surface of the $Cu(In,Ga)Se_2$ thin films is somewhat larger than the bandgap in the bulk of the material accompanied by a barrier for holes [26].

There is still no clear picture of the defect structure of the surface [26]. However, it is an accepted fact that grain boundaries and the heterojunction cause only small recombination losses. Due to the importance of the interface, the interaction with buffer layers is a key problem for device optimization. Here, CdS is still the standard for the high-efficiency devices. Careful optimization of the junction formation is needed for other compounds like InS and ZnS as buffer layers.

Grain Boundaries A further important feature of the material is the role of the grain boundaries [15]. Even in high-efficiency cells, grain size does not seem to play an important role for device performance [27]. A similar reconstruction in the grain boundary as assumed on the surface could also reduce recombination. Recent studies of the microstructure reveal a structural confinement at the grain boundary extending less than 1 nm. Even though substantial progress has been made with analytics on the atomic scale, detailed understanding of grain boundary properties is still lacking.

The Role of Sodium A very important impurity and the key to high efficiencies of CIGS-based devices is Na. The presence of Na either during film growth or in an annealing step afterward increases carrier concentration [28–30] or affects the crystallinity of the films. Soda lime glass is not only a very cheap substrate but also a very efficient source for Na. If other substrates like metal or polymer foils are used, methods for introducing Na by other sources like precursor layers are essential. The early thin-film devices were fabricated on alumina or on Na-free glass substrates. The influence of Na on the growth of $Cu(In,Ga)Se_2$ films was found some years ago [31]. When soda lime glass is used, Na from the glass substrate diffuses into the absorber. In order to better control sodium content, it is also deliberately incorporated in the film by the use of Na-containing precursors such as Na_2Se [32], Na_2O_2 [26], and NaF [33]. Among different alkali precursors, Na-containing precursors yielded the best cell efficiencies. The most obvious effects of Na incorporation are a reduced defect concentration and a higher conductivity of the films [29, 34]. Furthermore, the incorporation of Na affects the growth of the absorber films, for example, grain size and interdiffusion of In and Ga.

The explanations for the effect of Na are manifold, and it is most likely that the interaction of Na with the growing film has a variety of consequences. A basic process appears to be the reaction of Na with Se and the formation of intermediate compounds. During film growth, the incorporation of Na leads to the formation of $NaSe_x$ compounds. This slows down the growth of $CuInSe_2$ and could, at the same time, facilitate the incorporation of Se into the film [35]. The widening of the existence range of the α-($CuInSe_2$) phase in the phase diagram as discussed above, as well as the reported larger tolerance to the Cu/(In + Ga) ratio of Na-containing thin films, could be explained in this picture. Furthermore, the higher conductivity of Na-containing films could result from the diminished number of compensating Vse donors. The presence of Na has a significant influence on the kinetics during

formation of $CuInSe_2$ films from stacked elemental layers. Thin-film calorimetry [36] revealed that Na inhibits the growth of $CuInSe_2$ at temperatures below 380°C. The retarded phase formation due to stabilization of the intermediate binary Cu compounds is responsible for the better morphology in the case of Na-containing samples.

The amount of Na found in device-quality polycrystalline $Cu(In,Ga)Se_2$ films is of the order 0.1 at.%, which is a concentration of 10^{20} cm^{-3} [37]. Sodium is detected in grain boundaries or on the surface of the film. The effective doping resulting from Na incorporation leads to concentrations of $\sim 10^{16}$ cm^{-3}, four orders of magnitude below the absolute Na content. The main part of Na is incorporated on the film surface and the grain boundaries, as confirmed by various high resolution methods like secondary ion mass spectrometry, scanning Auger electron spectroscopy, or atom probe microscopy.

A further effect of Na is passivation of grain boundaries by oxygenation [38]. Reducing positive charge at the grain boundaries could lead to an enhancement of the net film doping by Na incorporation. Diffusion of Na into epitaxial $Cu(In,Ga)Se_2$ films at a temperature of 550°C decreases the degree of compensation by several orders of magnitude [39]. This effect could be attributed to a Na-enhanced reorganization of the defects, which allows them to build electrically passive clusters. Despite of the importance of Na for CIGS film formation and properties, the benefit is far from being explained in terms of simple models. In view of the amounts of Na (~0.1 at.%) necessary for preparation of films with optimum properties, the effect on film growth and control of defect formation are the most likely mechanisms. However, posttreatment of absorber films with Na significantly improves the performance of solar cells [40]. Most recent success in growing film at low substrate temperatures revealed the beneficial effect of Na when it is introduced at the end of the growth of the film [41].

Multinary Alloys Alloys of multinary chalcopyrite compounds allow all kinds of bandgap variations in the absorber film. The system of copper chalcopyrites covers the visible spectrum with a wide range of bandgap energies from 1.04 eV in $Cu(In,Ga)Se_2$ up to 2.7 eV in $CuAlSe_2$. Pioneering work on single crystals was performed by [42]. Varying composition during growth opens the possibility of bandgap engineering and the design of wide-bandgap devices in the $Cu(In,Ga,Al)(S,Se)_2$ system.

The energy gap of Cu chalcogenides as displayed above in Fig. 2 allows to produce any desired alloys between the compounds as there is no miscibility gap in the entire system. For efficient solar cells, $Cu(Ga,In)Se_2$ alloys provide design options for the absorber layer. Even though there is a significant change of the lattice constants upon alloying, there is no significant increase in the concentration of electrically active defects, even if strong gradients of composition exist. There is much room for device design and the need for working around limitations by processing the material in a way where defects are minimized.

In spite of the structural similarities, the different compounds have different electronic properties. In particular, the phase diagram of all chalcopyrite compounds is not necessarily as favorable for the electronic properties as $CuInSe_2$ [43, 44].

Survey of Absorber Fabrication Processes

Development of CIGS thin films has diversified in various directions already in the beginning. Not only coevaporation technology was brought to pilot production, but also various other deposition processes like sputtering, stacked layer annealing, screen printing, and electrodeposition were developed [45]. Main parameters for the growth of high-quality CIGS thin films are the proper supply of the metals in combination with the controlled interaction with the chalcogens either from the gas phase or from elemental layers.

Photovoltaic-grade $Cu(In,Ga)Se_2$ films have a slightly In-rich overall composition. The allowed stoichiometry deviations are astonishingly large, yielding a wide process window with respect to composition. This great tolerance of CIS to deviations to the stoichiometry is a prerequisite for the success of CIGS solar cell production. Devices with efficiencies above 18% are obtained from absorbers with ((In + Ga)/Cu) ratios between 0.95 and 0.8 provided the sample contains Na. Cu-rich $Cu(In,Ga)Se_2$ shows the segregation of a secondary $Cu_{2-y}Se$ phase preferentially at the surface of the absorber film. The metallic nature of this phase does not allow the formation of

efficient heterojunctions. Even after *removal* of the secondary phase from the surface by dissolving in KCN, the performance of Cu-rich material for photovoltaic applications is limited, probably due to the high doping density of 10^{18} cm^{-3} in the bulk and the surface defects. However, Cu-rich composition is important during film growth. Cu-rich films have grain sizes in excess of 1 μm, whereas In-rich films have much smaller grains. A model for the film growth under Cu-rich compositions comprises the role of $Cu_{2-y}Se$ as a flux agent during the growth process of coevaporated films [46]. This model for the growth of $Cu(In,Ga)Se_2$ in the presence of a quasi-liquid surface film of Cu_ySe assumes that the presence of Cu_xSe crystal growth is determined by this quasi-liquid surface phase which helps to incorporate In and Se in a liquid–solid growth mechanism. Because of the unique properties of the material connected with the necessity to control composition over large areas, many different processing options have been investigated [47]. Besides selenization and coevaporation, other deposition methods have been studied, either to obtain films with very high quality or to reduce cost of film deposition on large areas.

Coevaporation of the elements from single sources became a well-established process due to advances in source developments and process control. Besides the improvement of evaporation processes, other methods that use precursor-based technologies, i.e., conversion of metal films or printed particles including atmospheric pressure deposition also yield high-quality absorber material. This diversification is characteristic for CIGS technology. There are numerous companies worldwide, each with a different approach for CIGS fabrication.

Since absorber deposition is the limiting step for the throughput of the production line, tact time for in-line processes or the capacity of batch processing is an important parameter of production processes. Till now, both approaches are used in high production lines with capacities of 100 MW–1 GW. Figure 4 gives a schematic overview of deposition processes for CIGS films.

Growth of Single Crystals and Epitaxial Layers

The first photovoltaic device based on $CuInSe_2$ was a heterojunction with evaporated CdSon, a CIS single crystal [2]; high-efficiency single-crystal devices have never been reproduced. Various attempts to produce epitaxial films as a reference contribute to the basic understanding of the material [48] but did not result in the development of very high-efficiency devices. Epitaxial III–V compound films, grown by molecular beam epitaxy (MBE) [49] or metal organic chemical vapor deposition (MOCVD) [50], have revealed interesting features for fundamental studies, such as phase segregation and defect formation, but cannot be used to form the base material for high-efficiency solar cells.

Vacuum Evaporation Methods

The first thin-film cells were produced by evaporation of $CuInSe_2$ as a compound together with elemental selenium [51]. After the historic start with single-source evaporation and additional Se, coevaporation of the single elements became a viable method. First devices close to 10% efficiency have been fabricated with separate sources for the metals in connection with suitable control of vapor fluxes by electron impact emission spectroscopy (EEIS). Evaporation became a reliable method for absorber deposition due to the development of advanced evaporation sources for in-line deposition. Progress of process control allows very high yield of large-area modules at high throughput. Control of the fluxes of the elements in the vapor by atomic absorption spectroscopy, temperature control with pyrometers, and fluorescence allow deposition of films at high yield. For scalable production processes, a good control of film growth is essential.

Coevaporation Processes The absorber material yielding the highest efficiencies is $Cu(In,Ga)Se_2$ with a Ga/(Ga + In) ratio of ~30%, prepared by coevaporation from elemental sources. The process requires a substrate temperature of ~550 C for a certain time during film growth, preferably toward the end of growth. One advantage of the evaporation route is that material deposition and film growth take place during one processing step. A high reproducibility of the film properties is obtained if the evaporation rates and substrate temperatures are well controlled. A feedback control based on electron impact emission spectroscopy (EEIS), a quadrupole mass spectrometer (QMA), or an atomic absorption spectrometer (AAS) controls the rate of each source. The composition of the

Solar Cells, Chalcopyrite-Based Thin Film. Figure 4
Schematic view of deposition processes of the (**a**) sequential processes. Stacked metal layers are selenized and converted into $CuInSe_2$ in H_2Se atmosphere or Se is provided by a solid layer, and reaction kinetics is controlled by the annealing temperature and temperature profile. (**b**) In-line coevaporation

deposited material with regard to the metals corresponds to their evaporation rates, whereas Se is always evaporated in excess. An additional possibility to control the composition is to monitor the emissivity [52] or the optical reflectivity [53] of the films. At the transition between In-rich and Cu-rich composition, the thermal emission and optical reflection changes resulting in a change of substrate temperature at constant heating power or a change of heating power for keeping a constant substrate temperature. This behavior allows to adjust the process precisely because it can be used as an end point detection in the process sequence.

This precise control over the deposition rates allows for a wide range of variations and optimizations with different substeps or stages for film deposition and growth. In the most simple single-step process, all rates as well as the substrate temperature are kept constant during the whole process.

Advanced preparation sequences always include a Cu-rich stage during the growth process and end up with an overall In-rich composition in order to combine the large grains of the Cu-rich stage with the otherwise more favorable electronic properties of the In-rich composition [47]. The so-called Boeing or *bilayer process* [54, 55] starts with the deposition of Cu-rich $Cu(In,Ga)Se_2$ and ends with an excess In rate and a Cu-poor composition of the film. Another possibility is the *inverted process* where first $(In,Ga)_2Se_3$ (likewise In, Ga, and Se from elemental sources to form that compound) is deposited at a lower temperatures (typically around 300 C). Then Cu and Se are evaporated at an elevated temperature until an overall composition close to stoichiometry is reached [56]. This process leads to smoother film morphology as compared to processes starting Cu rich. The most successful modification of the inverted process is the so-called *three-stage process* [57]. In this process, In, Ga, and Se

are again evaporated at the end of an inverted process to ensure the overall In-rich composition of the film even if the material is Cu-rich during the second stage. The three-stage process currently leads to the best solar cells. In general, variations of the Ga/In ratio during deposition allow the design of graded bandgap structures. [58, 59]. However, the distribution of Ga in the depth of the film depends on various parameters such as substrate temperature, Na content, and deposition rate [60].

Reactive Film Formation The complexity of the equipment for coevaporation processes is reduced if the layer can be formed from elemental or compound precursor films. These precursor films can be formed by any method for thin-film deposition. For Cu(In,Ga)Se_2 prepared by selenization, the role of $Cu_{2-y}Se$ is similar to the coevaporation process [61], where Cu_xSe mediates the growth of the crystallites, during the selenization from solid Se films (RTP) or elemental evaporation from the gas phase, or therefore, growth processes for high quality have to go through a copper-rich stage and end in In-rich stage.

Selenization from Se Vapor The second class of absorber preparation routes separates of deposition and compound formation into two different processing steps. High efficiencies are obtained from absorber prepared by selenization of metal precursors in H_2Se [62–64] and by rapid thermal processing of stacked elemental layers in a Se atmosphere. These sequential processes have the advantage that approved large-area deposition techniques such as sputtering for the deposition of the precursor layers are applicable. The Cu(In,Ga)Se_2 film formation then requires selenization as a second step. This selenization step is crucial for the quality of the film.

The very first large-area modules were prepared by the selenization of metal precursors in the presence of H_2Se in the late 1980s, years ago [65]. Today, a modification of this process is the basis of a gigawatt scale production line [66]. First, a precursor stack of Cu, In, and Ga is sputter deposited on the Mo-coated glass substrate. Then selenization takes place under $H_2Se/H_2/Ar$ atmosphere. To improve device performance, a second thermal process under H_2S is added, resulting in an absorber that contains a Cu(In,Ga)$(S,Se)_2$ surface layer with a wider bandgap.

Annealing of Stacked Elemental Layers A variation of reactive film formation that avoids the use of the toxic H_2Se during selenization is the rapid thermal processing of stacked elemental layers. Here, the precursor stack includes a layer of elemental Se. The stack is then reacted by a rapid thermal process (RTP) in either an inert or a Se atmosphere. The highest efficiencies are obtained if the RTP is performed in an S-containing atmosphere (either elemental S or H_2S).

On the laboratory scale, the efficiencies of cells made by these preparation routes are smaller as compared with the record values obtained with coevaporated CIGS absorber layers. However, on the module level, coevaporated and sequentially prepared absorbers have about the same efficiency. Sequential processes need two or even three stages for absorber completion, often in different pieces of equipment. These additional processing steps may counterbalance the advantage of easier deposition of the metal layers by sputtering. The detailed and sophisticated control over composition and growth achieved during coevaporation is not possible for the selenization process. The reaction kinetics is controlled by the time and temperature of the annealing process. Fortunately, the distribution of the elements within the film grown during the selenization process turns out to be close to a certain optimum, especially if the process includes the sulphurization stage. Since the reaction for the formation of $CuInSe_2$ is much faster than that of $CuGaSe_2$, and because the formation of the ternary chalcopyrite phase starts at the reaction front with the Se at the surface, Ga is concentrated toward the back surface of the film. An increasing Ga content implies an increase in bandgap energy. The Ga gradient introduces a so-called back-surface field, improving carrier collection at the same time as minimizing back-surface recombination. In turn, S from the sulphurization step is incorporated at the front surface of the film, where it reduces recombination losses and also increases the absorber bandgap in the space-charge region of the heterojunction.

Nonvacuum Processing Developments of so-called low-cost processes include electrodeposition, [67–69] screen printing, and particle deposition [70, 71]. Electrodeposition is carried out in either one or two steps. Codeposition of all elements requires adjustment of

concentrations and complexing agents. The crucial step in all cases is final film formation in a high-temperature annealing process in Se-containing atmosphere. The recrystallization process competes with decomposition of the compound; therefore, process optimization is quite difficult. Cells with good efficiencies were obtained by a hybrid process combining electrodeposition of a Cu-rich $CuInSe_2$ film and subsequent conditioning by a vacuum evaporation step of In(Se) [72, 73]. Again, annealing of the films at elevated temperature in a suitable atmosphere is an important add-on to the low-cost deposition processes of the precursor film.

Large-Scale Processing

The advantages of thin-film technologies are related to high throughput processing in connection with a minimum usage of material. Analyzing the many approaches with "proprietary" methods for CIGS deposition, a convergence to a certain standard should be expected. None of the methods solves all the problems of CIGS technology and fulfills all the expectation. Present production lines which supply modules to the market look back to a very long history of R&D.

In the beginning of CIGS development, coevaporation was realized only for relatively small areas. Great efforts have been invested in the development of large-area in-line coating system that allows continuous coating of substrates with a width of 0.6 m. High-volume production by coevaporation has been already demonstrated in the 30–100 MW range. Figure 5 shows the schematic view of such a deposition system, where the substrates can be continuously processed in an air to air load-lock system [74]. An important component of this deposition system are linear evaporation sources that allow homgeneous deposition on wide substrates.

Several production lines use coevaporation. However, the ambitious plans of a 1 GW/a production are based on the technology with the longest experience for module production, namely, sputtered precursors and selenizaton/sulfurization processes [75]. The success of CIGS deposition techniques for high-quality material proofs the maturity of the equipment for handling complex multicomponent systems [76]. Furthermore, production lines with "nonvacuum processing" which use sputtering, electrodeposition, printing of precursor particles followed by a selenization/annealing step at high or even atmospheric pressure are put into operation. Most of these production lines use flexible foils for role-to-role processing, for example, Al foils [77]. They reached a remarkable efficiency of 17.1% [78]. Table 1 gives an overview about the different processes and the actual production capacities. Until now, even on the level of more than 100 MW/a production, the process of the future is not yet known. This diversification seems to be a specific feature of CIGS technology.

Substrates

Production lines for CIS technology use the substrate configuration. In this case, no transparent substrate is needed, and therefore wider choices for substrate materials are possible. Even though most production lines use glass substrates, many new lines are based on role-to-role deposition of either metal or polymer (polyimide foils). These foils are either integrated as single cells in a glass/glass module or laminated with foils to maintain

Solar Cells, Chalcopyrite-Based Thin Film. Figure 5
In-line co-evaporation processes with line sources for large-area substrates

Solar Cells, Chalcopyrite-Based Thin Film. Table 1 Processes and estimated actual production capacities (projections in brackets)

Process	Steps, precursors, or films	Complexity of equipment	Film quality and control
Multistage coevaporation	Binary chalcogenide compounds	High	Very high
Reactive annealing pure metal films	Sputtered metal or alloy films	Medium–high	High
Reactive annealing Se/S-containing precursors	Electrodeposited compound films	Low–medium	Low–medium
Reactive annealing particle precursors	Printed particles	Low–medium	Medium–low

flexibility. Fully integrated flexible modules are under development. Either metal foils with isolation barrier layers or nonconductive polymer films are used as substrate materials. A key issue for the substrates is the supply of Na during growth. For monolithic integration of cells, precise patterning of the films is necessary. Interconnection is selective patterning of the layers in the solar cell. Recent announcements claim outdoor stability of these flexible modules.

Junction Formation

Since pn junctions cannot be realized by simple extrinsic doping, solar cells have to be realized as heterojunctions. The band diagram of a typical CIGS-based solar cell is depicted in Fig. 6.

The highly conductive n-type window layer serves as transparent front electrode. Criteria for the quality of this layer are high transparency and conductivity. Furthermore, band alignment of the conduction band is essential for device performance, in particular, open-circuit voltage. Mismatch to the absorber layer is moderated by a suitable buffer layer. Due to the importance of the interface, the interaction absorber surface with buffer layers is a key problem for device optimization. Here, CdS is still the standard for the high-efficiency devices. Therefore, many production lines rely on chemical deposition of CdS. However, replacement of CdS is a major objective of actual developments. Improved understanding of the junction allows to use other compounds like InS and ZnS. The choices are Zn(OH,S) or InS(OH), mostly formed by chemical bath deposition. Partial replacement of ZnO in the window layer by (Zn,Mg)O helps to adapt these buffer materials [79]. Common observation with non-CdS buffer layers is an increased

Solar Cells, Chalcopyrite-Based Thin Film. Figure 6 Band diagram of a Cu(In,Ga)Se_2-based solar cell with ZnO window layer

tendency to light soaking effects, i.e., the efficiency increases during illumination.

Status of Large-Scale Production

CIGS is the only thin-film material that has the potential to compete with wafer-based multicrystalline silicon modules. In the production lines for CIGS, a continuous improvement of module efficiency is achieved. Large-area (0.8–1.5 m^2) standard modules approach 14% efficiency. Prototype modules with an area of about 900 cm^2 reach efficiencies of more than 17% [80]. Several production lines produce modules by different processes [81, 82]. The biggest manufacturing line for CIGS is operated by Solar Frontier in Japan [83].

Present Limitations

Limitations due to Material Properties

In principle, efficiency should not be limited by the material because of high radiative lifetimes and high mobilities. In present efforts, there is still room for improving material quality by better control of extrinsic impurities, quality of substrates and back contacts and growth processes. One major issue is the control of defects at wider bandgaps.

Limitations due to Availability and Environmental Issues

The availability of the elements indium and gallium topic is discussed quite intensely [84]. In principle, there is no real limitation by the natural resources, but there is the issue of production cost if the raw material prices rise. Since the thickness of absorber layers of present modules is redundant with respect to optical absorption, there is still room for saving material. However, reducing thickness may affect yield of the production so that only careful process optimization could lead to a benefit for the module cost [85, 86].

Perspectives

Due to the complexity of the material, great challenges cannot be met by simple engineering approaches but need disruptive solutions. On the one hand, CIGS offers many opportunities for future high-efficiency PV module development; on the other hand, one should be aware of the limitations implied by the self-organizing nature and flexibility of the material. There is still lack of understanding of major issues of material science, for example, the role of Na, the role of Cu in the metastable behavior of the devices and the properties of the heterojunction. Furthermore, limitations of wide-bandgap compounds still need investigation.

Efficiency

The possibility to adjust the bandgap to the optimum position in the solar spectrum at operating conditions and the favorable properties of the material should, in principle, allow efficiencies very close to the theoretical limit. A careful analysis of loss processes shows that losses occur in various parts of the heterojunction [87]. However, intrinsic properties of the multinary semiconductor may impose losses which have to be minimized by the proper choice of alloys and preparation methods. Since there is no ideal single-crystal reference available, it is very difficult to identify the relevant defects. Due to the low energy of formation of some defects, the defect concentration under equilibrium conditions depends on deviation from stoichiometry and will always remain on a certain level. The phase boundaries between chalcopyrite and the neighboring Cu-poor or Cu-rich phases according to the phase diagram are still not known precisely (in terms of doping concentrations). Compositional fluctuations on different scales in the film require to keep distance of the composition from the Cu-rich phase boundary to guarantee single-phase material. Therefore, one has to tolerate a higher density of Cu vacancy–related defects.

An efficiency >19% is reached on small area in several laboratories worldwide. Recently, 20% efficiency has been exceeded [6]. This progress is based on incremental improvements in the last 10 years when the efficiency has been increased from about 19% to 20.3% today. The actual parameters of the record device are still not optimum. Defect concentrations and, hence, efficiencies depend on many process parameters during device fabrication which are not yet completely understood. For exploring efficiency limits, it is important to understand more about defects and impurities in high-efficiency devices. Table 2 lists the IV data of high-efficiency devices fabricated in different laboratories.

A further remarkable achievement is the fabrication of an 18.7% efficient flexible solar cell on a polyimide foil substrate by the group at EMPA [42]. This solar cell was grown at low substrate temperature and optimized Ga grading together with well-controlled incorporation of Na.

Solar Cells, Chalcopyrite-Based Thin Film. Table 2 Summary of confirmed IV data of high-efficiency devices

Performance	ZSW [6]	NREL [88]	HZB [89]	Best values
V_{OC} (mV)	740	691.8	702.5	740
J_{SC} (mA)	35.4	35.74	35.63	35.5
FF (%)	77.5	81.03	77.52	81.0
η (%)	20.3	20.0	19.4	21.3

The big challenge is to develop a thin-film technology that combines all advantages of thin films with the performance potential of photovoltaics already demonstrated with high-quality crystalline materials. To some extent, this has been demonstrated for $Cu(In,Ga)Se_2$ laboratory scale devices. Taking the best values achieved by the different laboratories, an efficiency of more than 21% would be achieved. This simple calculation should be justified in view of the high fill factor expected at increased open-circuit voltage.

A major step forward would be the realization of monolithic tandem structures. The major issue is development of the high-efficiency wide-bandgap part of such a device. The alloy system with the elements Ag, Cu, In, Ga, Al, Se, and S, in principle, enables design of optimum combinations of bandgaps. However, in all development with varying alloy compositions, the efficiency of wide-bandgap cells drops at bandgaps beyond 1.3 eV, regardless of the compositions of the multinary alloy with the possible combination of the elements [90]. In contrary to thin-film amorphous silicon, deposition temperatures are too high for the straightforward fabrication of monolithic stacks. Continued research is important to develop solutions to this important problem. Following the rules for the fabrication of high-efficiency $Cu(Ga,In)Se_2$, efficiency could reach 18% at 1.3 eV [91]. Best efficiencies of wide gap devices with Eg> 1.5 eV $Cu(In,Ga)S_2$ reach close to 13% at an open-circuit voltage of 800–900 mV [92].

Modification of the Material System

$Cu(In,Ga)(Se,S)_2$ (CIGS) based solar cells reach efficiencies of >20% but might suffer from high material cost of In and Ga. Replacing these elements by abundant low-cost elements like tin and zinc without sacrificing performance would be an important step toward sustainability of this technology. Even though no shortage of raw materials (in particular, In and Ga) for CIGS technology is expected in the near and midterm future, replacing indium and gallium by abundant elements like tin and zinc would allow a sustainable development of thin-film solar cell technology also on the terawatt scale. New analytical methods and reliable equipment for thin-film processing and control facilitate control of thin-film processes for these new and complex materials [93]. Due to the similarity of most material properties, $Cu_2ZnSn(Se,S)_4$ (CZTS), in principle, could be handled in actual production lines with device structures similar to the state of the art CIGS modules [94]. It took 10 years to reach efficiencies close to 10% [95–98]. Recently, efforts for the development of this material significantly increased, and devices with efficiencies close to 10% were fabricated [99]. However, the complexity of the compound needs significant efforts in the design of processes for large-scale production and provides challenging tasks for the design of deposition systems and process control.

Future Directions

CIGS has proven to be the high-efficiency option among the thin-film photovoltaic technologies. The variety of material, device, and process designs opens many different ways for future developments. The future mainstream technology for the manufacturing of CIGS modules is not yet decided even though a 1 GW production is in operation based on the selenization of sputtered metal precursor films. The potential for large-scale manufacturing of other processes like coevaporation, electrodeposition, sputtering, or printing is also quite high, in particular, if role-to-role processing is considered.

Concerning efficiency of laboratory devices, there should be no reason for not getting close to the theoretical limit. Depending on the adjustment of the bandgap, 25% efficiency could be exceeded. In the midterm, module efficiencies of 17% should be reached; in the long term, a performance exceeding 18% on the production level is expected [100]. Further improvements beyond 20% efficiency are expected with multijunction devices.

Blackbody (BB) radiation Radiation in equilibrium with a perfectly absorbing (black) body at a given temperature T. The spectrum and intensity of the radiation is completely determined by T.

Detailed balance principe that imposes a relationship between any forward and backward reaction rates.

Epitaxy mode of crystal growth on a cristalline substrate, where crystal orderind is continued in the growing phase.

Impact ionization interband electron-electron interaction whereby the excess energy of a carrier is given off to another carrier in a low lying state to promote it in a higher band of states.

Multijunction Photovoltaic device composed of several sub cells. Most of the time, these are series connected and have semiconductor with different band gaps to address different parts of the solar spectrum.

Photon cutting process by which a given photon gives two photons of lower energies (obeying of course energy conservation).

Recombination process by which a (photogenerated) electron-hole pair is anihilated (the excited electron returns to its fundamental state).

Shockley–Queisser limit (SQ limit) fundamental limit on the photovoltaic conversion efficiency imposed on a single junction solar cell by the laws of physics.

Tandem synonyme of multijunction

Thermalization processes by which a system returns to thermal equilibrium

Upconversion process by which two photons are converted in a photon of higher energy

Definition of the Subject and Its Importance

The issue of photovoltaic conversion efficiency of solar energy has always been on top of priorities and might still be at this place for a while. First, devices had to display some efficiency to convince. Early in the XXth century devices using elemental Se were below one efficiency point. Only when devices' efficiencies exceeded 10% (in the 60') could PV start to develop as a credible energy generation route.

Since then, and till today with commercial device efficiencies in the 30% range, increasing solar cell efficiency remained an important way of reducing the cost of solar electricity (LCOE), albeit, not the only one.

And finally, the discussion around efficiency of solar energy conversion is fascinating because it delves with the principles of solar energy conversion and it tells us how long the road in front of us is and how bright the perspectives could be.

Introduction

Historically, PV developed in several stages. In early times, the problem was to find a system with reasonable efficiency. The photovoltaic effect was discovered in 1839 by Edmond Becquerel in a photoelectrochemical device [5]. It took several decades before solid-state systems were discovered. The first such system is based on elemental selenium and was discovered by D. Day (A.D. 1870) and developed by C. Fritts (A.D. 1883) with Se° wafers whose efficiency was probably below 1%.

Applications for electricity production did not take off before Chapin, Fuller, and Pearson demonstrated photovoltaic cells based on Si with efficiencies close to 5% (by Chapin, Pearson and Fuller, 1954). This was soon followed by the discovery of two other

material systems with similar efficiencies: AsGa at RCA (1956) and Cu2S/CdS by USAF (1955).

Achievement of significant efficiencies at the moment when satellites required powering prompted more research and led to a rapid development through the 1960s with eventually 14% efficient cells at the end of the decade. The oil crisis in early 1970s then prompted a renewed interest in terrestrial applications, with Si wafers and thin film–based technologies (a-Si, CdTe, etc.). A general historical account of PV can be found in [61].

In the 1980s, crystalline Si cells passed the 20% efficiency barrier. Importantly, this is also the decade when III–V cells demonstrated high efficiencies (>20%) and when tandem cells (devices using several junctions in series) were demonstrated. Cells under concentration passed the 25% barrier. Progress was continuous in this domain, and today, multijunctions achieved 43.5% under concentration and terrestrial applications are growing rapidly, nearing 100 MWp installed.

In terms of devices, it has been proposed to distinguish three steps or three "generations" of devices, providing a useful framework to discuss the various options to reduce the cost of photovoltaics [31].

Yet, albeit semiconductor devices enabled to make the first reasonably efficient systems, their fundamental limitation in converting efficiently a broad spectrum of radiation was evidenced early on [73]. The question of the limiting efficiency of solar energy has been debated at length since early times. We will give the main conclusions of these studies in a first part.

It was quickly realized that there are two ways to increase the efficiency:

- Concentration of solar power
- Use of an optimized semiconductor for each spectral band

The second part of this chapter deals with these two pathways. Combined, these have been extremely successful at demonstrating very high efficiencies, currently above 40% [78]. These high efficiencies are obtained at the cost of complex, technologically demanding, and in the end rather costly, devices.

It could be asked whether it is possible to achieve similar results, using different photovoltaic conversion principles, with simpler, and possibly cheaper, devices.

These are the questions we then turn to discuss by describing a series of proposed concepts (up and down conversions, intermediate levels or bands, multiple exciton generation, hot carriers, etc.).

The Shockley–Queisser Limit and Other Thermodynamic Limits

Thermodynamic Limits

Thermodynamics is the best framework to make general statements about energy conversion: actually, it was developed for that precise purpose.

One of its main achievements was to find that there is nothing like a free lunch and to quantify to minimal cost for energy conversion in terms of entropy production.

Now, although it is pretty clear what a thermodynamic cycle is for a motor, it is not so for photovoltaic conversion: does light have thermodynamic properties like temperature and pressure?

Indeed, and the realization of that marked the passage into the twentieth-century physics, from the classical to the quantum world.

An excellent discussion can be found in [31].

Carnot

Does this limit apply to photovoltaic conversion? Carnot process deals with heat exchange, and a solar cell is very different from a heat engine, or so it seems, and proceeds via transformation of radiation into electrical work. But the sun radiation is very close to a blackbody spectrum, with a temperature $T_s \sim 6{,}000$ K, and the electrical work is delivered at ambient temperature (around $T_s = 300$ K). Carnot limit (95% = $1-T/T_s$) has to apply to photovoltaics, otherwise it would be possible to beat the Carnot limit for any thermal source using thermal radiation. This 5% loss originates from the unavoidable heat flow and subsequent entropy production when work is produced using heat sources and sink. As we will see below, a lower limit is to be found.

Blackbody Limit

A more reasonable limit (the endoreversible limit, or thermal limit) is given by

$$\eta_{\text{therm}} = \left(1 - \frac{T_a^4}{T_s^4}\right)\left(1 - \frac{T}{T_a}\right) \quad (1)$$

where solar flux heats up an absorber (at temperature Ta, which can also reemit blackbody radiation), and a Carnot engine operates between Ta and the cold sink (at T ~ 300 K).

The maximum efficiency is ~85%, obtained for Ta ~2,500 K (Landsberg, De Vos, etc.).

The difference with the above Carnot limit is that in the former, the sun's surface was included in the thermodynamic device and the Carnot engine works reversibly with the Sun, a quite preposterous assumption.

Multicolor Limit

It is also possible to build (as a thought experiment) a device doing even better than the previous one in converting radiation into electrical work. This can be obtained by separating the light in its different components and having each wavelength drive a solar cell whose gap E_g matches perfectly the energy of the incident photons [31]. This way, all the solar spectrums can be absorbed while thermalization losses (originating essentially from the excess energy between that of the incident photon and the energy that can be harvested, lower than E_g) are minimized. A slightly better efficiency than with the blackbody limit, ~87% (the "multicolor limit"), is then obtained under maximal concentration, and ~68% can be obtained without concentration. This is at the origin of the multijunction approach (see below). The losses here originate from recombination and, in the best case, from radiative recombination that are unavoidable: light has to be reemitted toward the sun as part of the conversion process.

Landsberg Limit and Time Reversibility

A higher limiting efficiency of 93.3% can in principle be achieved, using non-time-reciprocal optics to convert most of the light reemitted by the absorbers [31]. This limit is given by:

$$\eta_{\text{Landsberg}} = 1 - \frac{4}{3}\left(\frac{T_{\text{ambient}}}{T_{\text{sun}}}\right) + \frac{1}{3}\left(\frac{T_{\text{ambient}}}{T_{\text{sun}}}\right)^4 \quad (2)$$

Classification of Losses in Semiconductor-Based Devices

Intrinsic: Losses that Cannot be Avoided, Even in Principle

- Net Absorption Losses (Absorption and Luminescence Losses) In semiconductors (organic or inorganic), there is an absorption threshold, or band gap (E_g): photons below E_g are not absorbed while those above can be absorbed. Ideally, they could all be absorbed. Conversely, those of energy below E_g are lost for photovoltaic conversion as they cannot be absorbed. Unless $E_g = 0$, some photons will be lost, but with $E_g = 0$, a semiconductor yields no power (remember that the energy harvested per photon is smaller than E_g).

  If photons are reflected or emitted by the device, their energy is also lost. While reflection losses can be, in principle at least, reduced to nothing, this is not so with luminescence. Because photons can be absorbed to produce an electron and a hole, due to the microreversibility principle, there is a finite probability that an electron and a hole can recombine and produce a photon that escapes the device. It turns out that this is not a negligible quantity, and especially in very efficient devices, operating close to the radiative limit. This characteristic is the core of the detailed balance model (see below).
- Relaxation/Thermalization Photogenerated carriers have generally a kinetic energy much larger than the average kinetic energy of carriers of the same type present in the absorber (~kT) just after absorption. They will lose this excess kinetic energy by collision with other carriers or with atoms. The energy lost by this process per photon absorbed is essentially given by the difference between the average energy of an absorbed photon and E_g (–3 kT, the equilibrium kinetic energy of an electron–hole pair).
- Collection Losses Almost each and every electron–hole pair photogenerated can in principle be collected at the contact in good devices (provided for instance that the mobility and the carrier lifetimes are large enough). But while each electron–hole pair photogenerated has a total energy of about the bandgap after thermalization, only a fraction of that, the device voltage (i.e., the free energy of the pair), can be recovered as electrical power. The difference is

related to the entropy of the electron–hole pair times the carrier temperature. Moving the carriers from the absorber to the contacts (i.e., collection) involves an entropy change that has to be accounted for. The smaller the carrier concentration in the absorber, the larger the change and the smaller the output voltage.

Extrinsic: Losses that Could, in Principle, Be Made Vanishingly Small

- Optical Losses Encompass parasitic absorption (e.g., in parts of device where it is immediately dissipated, as in metal contacts) and reflection. They result primarily in a current loss.

  Reflection losses can be made near zero using efficient antireflection coatings. While parasitic absorption can, in principle at least, be vanishingly small.

  Moreover, if a fraction of the photons of a given energy is not used to create an electron–hole pair, this is clearly suboptimal; therefore, absorptivity of the active material should ideally be either 0 (under the absorption threshold) or 1 (above). This situation can be approached with adequate light trapping.
- Nonradiative Recombination Losses originate from nonradiative processes, where an electron and a hole recombine without emitting a photon, yield primarily a voltage loss but also a current loss. They result in additional losses as compared to pure radiative recombination (mandatory for consistency: detailed balance rule, and has to be accounted for, as discussed above). They can be made very small in some systems such as molecular systems or in very high-quality semiconductors of the III–V family. Such recombinations contribute to heat dissipation, and are therefore also nonoptimal.

  In the following, we will most of the time consider only radiative processes. Other processes only serve to get faster to equilibrium and therefore produce additional entropy. As we are here interested in conversion limits, we will not consider them here.
- Electrical Losses Occur because current flow in a conductor goes with and ohmic drop, which is a voltage loss. Charge transport can be made with negligible ohmic losses in devices with a high enough carrier mobility.

  Parasitic electrical path usually exists in devices and can create short circuiting between the electrodes.

  Different parts of a device act as if they were connected in parallel. If the device is heterogeneous, this may result in an impedance mismatch between its different parts and therefore in a suboptimal working point, as compared to what could be achieved with a homogeneous device.
- Thermal Losses Occur because of the dissipation of power (*thermalization*), photovoltaic devices become warmer under operation, and this is detrimental to the conversion efficiency. Yet, in principle, the device could be efficiently coupled to a thermostat and its temperature uniform and fixed at a given value, so variations in temperature are often ignored. These could be of importance in solar cells working under high solar flux (as in CPV or concentrated solar power).

The SQ Limit

The fraction of energy that can effectively be converted by an absorbed photon, qV/hν, is therefore much smaller than its maximum value because the free energy obtained from each photon is independent of its energy (the remainder goes to the atomic lattice heat in less than a few picoseconds, during carrier thermalization). Including the fraction of the photons that is not absorbed, the efficiency is limited to ~30% for the optimal gap E_g under standard conditions of illumination [73]. In short, this limit can be derived provided some idealizations are made so as to focus on intrinsic losses and neglect extrinsic losses (those that can, in principle, be made vanishingly small):

- Negligible ohmic losses: a high carrier mobility is assumed.
- Optical losses such as reflection or parasitic absorption are very small. Moreover, absorptivity of the active material is either 0 (under the absorption threshold) or 1 (above).
- The quantum efficiency of the device is equal to the absorber's absorptivity (perfect collection).
- Losses from nonradiative processes are neglected.
- The device is efficiently coupled to a thermostat.

The system studied entails some intrinsic losses:

- Below gap photons are not absorbed.
- Some photons are absorbed, leading to the reverse process of photon emission and therefore radiative

losses. Losses are incurred by establishing an equilibrium between the generated photocarriers (whose average kinetic energy is generally significantly larger than $\frac{3}{2}kT$) and the lattice. This is generally called "thermalization losses."

- The free energy collected per electron–hole pair (the cell voltage) is lower than the bandgap of the semiconductor (i.e., the energy of the pair). This is called "collection losses" and is ultimately due to the finiteentropy loss associated with carrier collection.

When these simplifying (but physically consistent) assumptions are taken into account, one obtains the so-called Shockley–Queisser limit [73], that is, the maximum value of the electrical power that a p–n junction can generate under solar illumination, depicted Fig. 1.

Detailed Balance. The principle of detailed balance has been stated in many different forms (e.g., by Onsager). In essence, it stems from the fact that no work can be extracted from equilibrium: it follows that, at equilibrium, each microscopic process has to be compensated. This compensation could be global (say, optical generation of an exciton compensated by nonradiative recombination). The detailed balance principle states that each process is compensated at equilibrium by its reverse process.

A consequence is that if an elementary process leading to energy flow between states is possible, then its exact reverse is also possible and occurs with the same probability: the rates of a process and its time reverse are therefore related (the transition matrix elements are equal). If then radiative recombination

Solar Cells: Very High Efficiencies Approaches. Figure 1
Limiting efficiency of p–n junction solar cells as a function of the bandgap of the absorbing material, taking into account only unavoidable losses, under AM 1.5 illumination at 300 K. The crosses mark the efficiencies achieved for Si and GaAs cells. The blue continuous line is the Shockley–Queisser limit, that is, the maximum fraction of the incident (here, AM 1.5) flux that can be converted. The *green dashed line* gives the fraction of the incident power that is not absorbed by the photoactive material. The *red dashed line* gives the fraction of the incident power that is thermalized as a result of the excess initial energy of the electron–hole pair formed after photon absorption versus its equilibrium value (i.e., hv- E_g-3kT). *The blue dashed line* gives the fraction of the incident power that is lost through radiative recombination. The purple dashed line gives the fraction of the incident power that is lost during the process of carrier collection in the photoactive material or in the contacts (i.e., E_g + 3kT-qV, where E_g + 3 kT is the average energy, potential and kinetic, of electron–hole pairs after thermalization and qV is the work effectively extracted). These collection losses are sometimes divided into "Carnot" and "Boltzman" losses (Hirst 2010); they depend on the illumination level of the solar cell

processes only are considered, the balance on photons gives the balance on charge carriers as:

$$I = q(\Phi_{\text{abs}} - \Phi_{\text{em}}) \tag{3a}$$

$$I = q(\Phi_{abs} - \Phi_{em})$$

$$\Phi_{abs} = \int A(E).\ \dot{N}_{inc}\ (E).dE$$

$$\Phi_{em} = \int \epsilon(E).\ \dot{N}_{em}\ (E).dE$$

$\dot{N}_{inc}\ \dot{N}_{em}$ are, respectively, the incident and emitted photon flux densities, and A(E) is the photoactive materials' absorptive. It actually follows from detailed balance that A(E) = ε(E). This is also called Kirchhoff's law.

Equation 3a shows that the electron flux I is simply equal to the difference between the fluxes of photons absorbed, Φ_{abs}, and photons emitted, Φ_{em}. When the electron population of the absorber (which is also an emitter by virtue of the detailed balance principle) is in thermal equilibrium, Φ_{em} expresses the *law of black-body radiation*. When it is not, but the electron and holes populations can be ascribed to a quasi Fermi level each, $\dot{N}^{em}$ is given by [88]:

$$\dot{N}^{em}(E) = 2\pi h^3 c^2 \frac{E^2}{e^{(E-\mu)kT} - 1} \tag{3b}$$

where $\mu = E_{fn} - E_{fp} = qV$.

The electrical power extracted from a photovoltaic device is

$$P = I.V = \mu.(\Phi_{abs} - \Phi_{em}(\mu)) \tag{4}$$

From Eqs. 3 and 4, using the AM 1.5 spectrum for incident photon spectrum, one can recover the Shockley–Queisser limiting curve as in Fig. 1.

Another situation of interest is that of a monochromatic incident photon flux incident on a two-level system tuned to absorb it (see scheme Fig. 2), as it is of general and fundamental significance because it enables the calculation of the maximum value of free energy that can be extracted for each absorbed photon, μ_{opt} (Fig. 2), independently of the conversion system [31]. This free energy depends solely on the energy of the photon and the incident flux, and it can be computed using Eqs. 3a and 4 applied to a two-level system [19]. The conversion efficiency of a two-level system under monochromatic light can be read from Fig. 2; it is simply $\mu_{\text{opt}}(E)/E$ per collected electron hole pair and $\mu o/E^{*}1/(1+kT/\mu o)$ per absorbed photon.

With the help of Fig. 2, it can be calculated that the maximum efficiency ("multicolor limit") of a photovoltaic device is 67% under standard solar illumination and ~87% under maximum concentration

Solar Cells: Very High Efficiencies Approaches. Figure 2
(**a**) Scheme of the two-level systems considered. (**b**) Recoverable optimal free energy μ by an absorbed photon, that is, at the maximum electric power extraction (ordinate, *left axis*), according to both the photon energy (abscissa axis) and the incident photon flux (different *curves*). *The blue curve* corresponds to a 6,000 K blackbody spectrum, the *red curve* to the terrestrial solar intensity, and *the black curve* with that of solar flux above the atmosphere. *Green curves*: the photons fluxes on a log scale (*right axis*) for the same spectra (From Guillemoles 2009)

as the weighted (by the photon flux) average of μ_{opt} divided by incident power. The fact that no such efficiencies have been approached yet is because the materials and technologies were not ready to meet the severe specifications necessary (as described in the assumption list above). Clearly, following the way suggested by the method used in deriving the result to realize a device would be very difficult in practice.

Main Paths

Impressive progress, at an average rate of 0.4% per year, has been made on the efficiency of solar cells. Record efficiencies above 43.5% have been obtained by Solar Junction recently, but many Labs and Companies now make solar cells working under high concentration with efficiencies above 40%, using a variety of approaches, with multijunction solar cells based on III-V semiconductors. This makes III-V multijunction the path with the fastest progress at the moment. It shows how successfully the knowledge gathered on these materials and on similar devices for other applications (LED and Lasers notably) could be put to use in the photovoltaic context.

It should be stressed that this progress is due to two factors: the ability to use concentration to increase efficiency and the use of several semiconductors to make a better use of the solar power, reducing thermalization and non absorption losses as compared to single junctions. Indeed, the best triple junction under one sun illumination (presented by Sharp Corp.) has a confirmed efficiency of 36.9% (as compared to 28.2% for the best single junction under one sun [72]). Thus, about as much is gained going from one to three junctions as is gained between one and 400 suns.

Concentration

Solar concentration is a primary driver towards high efficiency. Indeed photovoltaic efficiency is not a constant, but rather depends on the incoming light flux intensity. This is reflected in Fig. 2, where it can be seen that the maximum recoverable work per photon (μopt) increases when the photon flux increases. This can also be seen from Eqs. 3a, b: since the recombination current increases exponentially with the electron–hole gas chemical potential μ, the μ value needed to cancel a given fraction of the photocurrent increases logarithmically with the photocurrent (which itself is proportional to the flux).

The cell voltage can be identified with the difference in chemical potential of electrons in the conduction band (CB) and of the electrons in the valence band (VB). These chemical potential difference, μ, increases with the incoming flux as the CB is populated (increasing Efn: the chemical potential increases with the concentration) and the VB depopulated (decreasing Efp). This increases amounts typically to +2 efficiency points per concentration decade.

Concentration is about increasing the inflow of radiative power in the device. In a certain sense it is akin to increasing the source temperature, and, taking an analogy with a Carnot engine (as e.g., in Eqs. 1 and 2), this results in an increased conversion efficiency.

But increasing power inflow means that the power outflow also needs to be increased. It occurs as electrical power and waste heat, and both extraction need to be efficient. An inefficient electric power extraction results in series resistance losses as Joule heat and a reduced electromotive force of the device. It manifests itself as an inflexion, then a plateau and finally a drop on the efficiency versus solar concentration curves (Fig. 3).

Limits of extraction of waste heat results in an increase of the device temperature. Taking again the Carnot engine analogy, this should result in an efficiency loss. It manifests itself on Fig. 6 as an accelerated drop of efficiency when the temperature start to increase.

Practical limits to concentration are set by heat and electrical power extraction, as explained above. Nevertheless, there is a fundamental limit to solar concentration set by thermodynamics: the energy density at the focal point of the concentrator cannot exceed that of a blackbody at sun's surface temperature (otherwise we could have heat to flow from the colder sun to the hotter focal spot). This limit is achieved at a concentration 46,200 times the standard if the focal point is in air.

There are several types of concentrators, based on lenses or/and mirrors. Most systems are based on Fresnel lenses (Fig. 4) that enable to reduce the cost: these can be easily molded and require much less material than traditional lenses. For high concentration (> x100), they are used as a primary optical

Solar Cells: Very High Efficiencies Approaches. Figure 3
Efficiency-concentration data of champion certified cells in the world (From [54])

Solar Cells: Very High Efficiencies Approaches. Figure 4

element (POE) and associated to a secondary optical element (SOE) to improve uniformity and tolerance to tracking errors (Fig. 5).

Modules for concentrated photovoltaics (CPV) have to be precisely aligned optically. They are then mounted on sun trackers (Fig. 6) to ensure that the solar flux is focused on the solar cells at any moment.

It should be noted that this approach only works with the direct component of the solar radiation, and misses out the diffuse part (due to cloudiness of the sky, or emanating from the blue part of the sky). On the nice side, CPV modules being at all times normal to the sun's rays, produces close to their nominal capacity from sunrise to sunset, yielding 30% more power than fixed, flat plate, modules.

Multijunctions

Principles and Achievements In a traditional device, the photons whose energy conversion is most effective are those whose energy is just above the threshold of absorption (bandgap energy E_g). For those photons, efficiencies of about 60% are reached in experiments, rather close to expectations (Fig. 2). The use of several different cell materials, each one with a bandgap optimized for a part different from the solar spectrum, makes it possible to increase the output power using several configurations.

Solar Cells: Very High Efficiencies Approaches. Figure 5 Scheme of the principle of a concentrator with secondary optics with mirrors in a Cassegrain configuration (The Solfocus design). The Glass rod further increases the concentration and the homogeneity of the beam

Several configurations are possible (Fig. 7): (a) An optical device separates sunlight by means of filters in three beams "blue," "green," and "red," which are converted by three cells whose bandgaps were adapted for these three spectral bands. One can simplify the device as indicated in (b), noticing that the "blue" cell does not absorb the wavelengths higher than its threshold of absorption. It can thus be used as filter for "green" and "red" cells. In the same way, the "green" cell lets the "red" beam pass. It is necessary, of course, that the substrates of the first two cells are transparent. Finally, in (c), a transparent electrical contact between the cells is realized. One can achieve this stack by deposition of the various cells on the same substrate. To avoid creation of a reverse diode at the interface between two cells (a diode p–n if diodes n–p are piled up), one connects them by a tunnel junction. In case (c), the cells are connected in series, whereas in case (a) or (b) one remains free to use the electricity produced in the most effective way.

For a given number of cells and an incident spectrum, there is an optimal choice for the gaps that give the highest output [31]: For example, for three cells under maximum concentration, the maximum theoretical yield is 63% (49% without concentration). As a general rule, stack efficiency goes as (see also [7]):

$$\eta(N) = \frac{\eta^{\infty}}{1 + \frac{a}{N}} \tag{3}$$

where a ≈ 1 and depends slightly on solar concentration. This formula expresses that, for a multijunction device composed of N junctions to operate optimally, the incident spectrum should be partitioned into $N + 1$ portions containing about the same fraction of photons, with the upper limits of the N first regions giving the optimal gaps of the absorber materials to be chosen for the junctions.

Moreover, in the tandem, the current is lower (for a given number of photons of incident) and the tension higher than for a simple junction device. This is favorable to the use of the concentration, which even allows a reduction of the costs.

This pathway to high efficiency is based on what exists and is already understood rather well.

It takes advantage of a large body of knowledge that has been developed for III–V optoelectronics, as well as for this purpose. There are several pathways to achieve an optimal current matching while keeping the very high material quality required for very high conversion efficiencies.

Highest material quality and best optoelectronic properties are obtained in extremely pure and well crystallized III-V semiconductors, and these are prepared using epitaxial growth: a technique where the grown material continues the crystallographic arrangement of the substrate. This imposes that substrate and grown compounds have very similar crystallographic systems and lattice parameters. It therefore restricts considerably the possibilities of growth.

Figure 8 presents the combinations of band gaps and lattice parameters for main III–V semiconductors. The bandgap determines how the solar spectrum is split between the cells in a multijunction (see Fig. 7 for a triple junction). The lattice parameters should be equal to within a fraction of a % if high quality material is to be obtained. A non optimal splitting and/or a non optimal lattice match can result in large losses, finding the best material combination has been the main

Solar Cells: Very High Efficiencies Approaches. Figure 6
Installations from Soitec-concentrix (*top*) and Solfocus (*bottom*) showing the modules and traking dimensions and installations

problem in the field to obtain the highest efficiencies possible (that is 50% under one sun for a triple junction). Sticking to possibilities offered by Fig. 8 restricted the efficiencies to little better than 35%. New strategies involve metamorphic growth (growth of a buffer layer with a continuously varying lattice parameter that accommodates the crystallographic changes between active materials), or the inverted metamorphic variant, lift off (where active materials are grown on lattice matched substrates, and then lifted-off and reported on the final structure), use of meta-materials made from quantum wells or quantum dots or development of new materials (such as dilute nitrides). The challenges are well known:

- The cost of production has to be reduced (reduce substrate cost, lower cost processing, etc.).
- Reduce electric and optical interconnection losses.
- Improve intercompatibility of the growth methods for stacks.
- Improve the efficiency via a better match with solar spectrum (keeping a high crystalline quality).
- Achieve higher concentration.

Why Beyond Multijunctions? It must be realized from Eq. 3 that the incremental gain in power from the addition of a cell in a stack including N junctions varies as $1/N$. If one takes into account the induced losses (electrical and optical), the expected net gain from another cell is close to zero after the fourth cell (i.e., the practical limit on N is 4).

$$\eta(N) = \frac{\eta^{\infty}}{1 + \frac{a}{N}}$$

Another point is that the tandems "stack" series-connected, which have the best prospects for the reduction for the costs become very sensitive to spectral variations (the complete structure must be optimized precisely according to the incidental spectrum), and this more especially as the number of cells is important.

Solar Cells: Very High Efficiencies Approaches. Figure 7

Principle of multijunction conversion (specifically for a triple junction) and possible practical configurations thereof: (**a**) An optical device separates sunlight by means of filters into three beams, denoted *blue*, *green*, and *red*, which are converted by three cells whose bandgaps were adapted for these three spectral bands. One can simplify the device as indicated in (**b**), noticing that the *blue cell* does not absorb the wavelengths higher than its threshold of absorption. It can thus be used as filter for the *green* and *red cells*. In the same way, the *green cell* lets the *red beam* pass. It is necessary, of course, that the substrates of the first two cells be transparent. Finally, in (**c**), a transparent electrical contact between the cells is realized. One can achieve this stack by deposition of the various cell materials on the same substrate. To avoid creation of a reverse diode at the interface between two cells (a p–n diode if n–p diodes are piled up), one connects them by a tunnel junction. In case (**c**), the cells are connected in series, whereas in cases (**a**) and (**b**), one remains free to use the electricity produced in the most effective way (From EPN 2009 (**d**) The solar spectrum and its partition between three junctions as in present-day highly efficient devices. A typical such structure is a stack of about 20 layers, epitaxially grown on a crystalline substrate (e.g., Ge, from which the bottom junction is made) forming p–n junctions of adjusted bandgaps for photon conversion (generally GaAs and $GaInP_2$) and tunnel junctions to connect them

New Concepts

Classification of New Concepts

There are many possible strategies to achieving very high-efficiency solar devices, many of which have ultimate conversion efficiencies close to 85%. All concepts essentially fall in three main groups (below) according to the assumption of the SQ analysis that is relaxed (Fig. 9):

1. Several electrons collected per photon
2. Subgap photons can produce collectable electron–hole pairs
3. Nonisothermal devices

Solar Cells: Very High Efficiencies Approaches. Figure 8
Combinations of bandgap and lattice constant for various materials used in III–V solar cells. The potential substrate materials silicon (Si) and germanium (Ge) are also indicated. As an example, the bandgap combinations of the lattice-matched triple-junction solar cell on Ge as well as of a metamorphic triple-junction solar cell developed at FhG-ISE are indicated. The *upper cells* of the metamorphic solar cells have a lattice-mis-match of 1.2% compared to the Ge substrate. In order to achieve sufficient material quality, a buffer layer is intregrated into the structure (From [54])

Solar Cells: Very High Efficiencies Approaches. Figure 9
Scheme illustrating the relationships between main conversion concepts and relaxed assumptions in the SQ analysis

Multiphoton Conversion (QE < 1)

Intermediate-Level Materials

Proposals have been made to better utilize the low energy part of the incident solar spectrum by using Intermediate Level Semiconductors (ILSC) either with localized states [41] or delocalized ones [43, 55]. It has been shown that such concepts have efficiency expectations up to 49% in an optimal device [31], comparable to those of triple junction devices (51%) under Air Mass 1.5 (AM 1.5) standard terrestrial solar radiation [31]. Indeed, these intermediate-level materials also have three possible optical transitions that may be adjusted to optimally use the solar spectrum. Contrary to multijunction devices, only one absorber material is needed, a fact which limits optical losses, tunnel junction losses and would help to design simpler, possibly cheaper, elaboration schemes. However, approaching those values would require rather low nonradiative recombination rates as compared to the radiative ones [41], a fact which has so far impeded the development of ILSC devices: without a specific mechanism to prevent them, nonradiative processes are far more efficient than radiative ones, especially those that involve the intermediate levels.

At this stage, intermediate level or bands that have been tried experimentally suffer both from a low absorption of the transitions involving the intermediate levels and a high rate of nonradiative recombination they induce so that in the end the losses they cause outweigh largely the small gain in photocurrent that is at best measured Fig. 10.

Upconversion Fig. 11

In the "upconversion" or "photon addition" approaches, the photons whose energy is too weak to be used directly by a photodiode could be converted by nonlinear processes into a lower number of photons of larger energy.

Early attempts were done [25, 26, 71], proving feasibility of the concept but with a limited success in terms of absolute efficiency gains: approximately 3% of the IR photons in the narrow band of absorption of proposed rare earths, under an illumination equivalent to 250 suns, were actually converted into photons of higher energy. Recently, power efficiency of upconversion from 15 to 1 μm have been demonstrated using CaF2:Er material [62]. Also, using plasmonic resonators, a large enhecement factor was demonstrated on YF3:Er [1].

Most of the research on the subject is done using systems containing rare earths and taking advantage of the processes of transfer of energies between rare earths. Molecular systems have also been considered.

Nonlinear optical systems taking advantage of polarizabilities of the second or third order have capabilities of conversion of broader frequency bands but are not very effective unless unrealistic intensities of illumination would be used (not achieved with a solar source).

A last category of process is represented by the phenomena of absorption of excited state which one can meet in the solids [80] but also in many molecular species [3, 21, 39, 85]. In particular, systems presenting

Solar Cells: Very High Efficiencies Approaches. Figure 10
Schematic representation of generation recombination processes in a standard semiconductor (*left*), a semiconductor comprising an intermediate band through which additional generation and recombination can occur (*middle*) and a spin polarized semiconductor where some of the recombination processes are blocked due to spin selection rules (*right*)

Solar Cells: Very High Efficiencies Approaches. Figure 11 Higher limits of conversion efficiency for upconversion systems as a function of the gap of the solar cell in the case of the angular restriction of emission (*squares*), and various concentration factors (1, 100, 46,200 times, *round blacks*). For comparison, the limits of outputs for a simple junction within the limit of Shockley for the same concentrations (*lines*) are also given (From [79])

Solar Cells: Very High Efficiencies Approaches. Figure 12 The excess energy of a photogenerated carrier (*yellow arrow*) is given off to a carrier in the valence band, creating a second electron hole pair

a small relaxation of the first excited state, such as, for example, the passage to triplet state, which sometimes makes it possible to increase its lifetime considerably and thus the probability of the excited state absorption, are particularly interesting. Yet, upconversion in organic systems was found to have issues related to molecular stability.

In the case of certain organic molecules, absorption cross sections of excited state as large as 10^{-16} cm^2 and μs lifetimes were measured. One thus expects an efficient conversion of IR photons for photons' fluxes of about 10^{22} cm^{-2} s^{-1}, which is approximately what is achievable with the maximal concentration of solar radiation.

To summarize, upconversion has a strong potential for efficiency increase of single junction devices, and this improvement can be implemented as a supplementary layer with minimal interference with the photovoltaic p–n junction. Yet systems that have demonstrated any efficiency suffer from either narrow band absorption or from large internal dissipation (so that the upconverted photon has hardly more energy than the source photons).

These systems see their efficiency increase rapidly with illumination intensity (power delivered increases at least as square of intensity, and sometimes as cube or more for 3 photon processes and more) before saturation or degradation, so that high incident flux is preferred.

Finally, optimizing the coupling to the cell, a domain with potential large losses, has hardly been done [62].

Multicarrier Generation (QE > 1)

Multiple Exciton Generation

The absorption of photons having energy more than twice that of the gap makes it possible to consider other mechanisms, where the excess energy can be used to create a second electron–hole pair. This phenomenon is called "impact ionization" (Fig. 12). The outputs of devices with impact ionization can have practical interest, provided that the process is effective in the vicinity of the physical threshold (~2 E_g). Work at the Max Planck Institute of Stuttgart predicted that the alloys Si-Ge could show a measurable effect. But this was found to be lower than 1% of the output power of cells made of this material. High values of impact ionization have so far been observed only for energies of photons higher than 3 E_g [46, 68, 86] (Fig. 13).

Recently [70], a working device based on PbSe quantum dots demonstrated a photocurrent increase

that could be traced back to multicarrier generation (peak external quantum efficiencies of 114% were measured). The device efficiency did not exceed 5%.

Photon Cutting

Another principle, "photon cutting" consists, conversely, in absorbing photons of high energy in a luminescent converter to emit several photons of lower energy, to increase the current output of the photodiode (Fig. 14).

Solar Cells: Very High Efficiencies Approaches. Figure 13 Impact ionization efficiency in PbSe nanocristals. The threshold for the formation of the second electron-hole pair is relatively abrupt at 3 times the gap E_g and is larger than 100 % for photon energies lower than 4 times E_g

Fluorescent converters with quantum yield <1 already made it possible to show an improvement of the performances of the solar cells while shifting toward the red of the photons slightly used by these cells [57]. In addition, of fluorescent materials with quantum yield >1 were discovered in the recent years:

- YF3:Pr with QE = 1.4 [75]
- LiGdF4 with QE = 2 [83]. The measured quantum yield corresponds to the quantum yield of internal energy transfer but not to a real output of photons.
- Nanocrystals of PbSe with QE > 2 for hv > 3.E_g [68].

However, although high quantum yields (close to 2) were reached, it should be noted that the energetic efficiency is not very good: less than 70% at best of the total energy of the source photon is recovered in the emitted photon due to internal relaxation processes. There are numerous challenges to this approach, notwithstanding the process efficiency itself (powerwise). Firstly, the converter is placed in front of the cell, and can easily interfere with the device quantum efficiency in all spectral ranges. The converter will absorb light at the photon energies where it emits (that is where photon cutting occurs). The optical coupling with the cell

Solar Cells: Very High Efficiencies Approaches. Figure 14
Schematic representation of a down conversion system. The converter can be in front of the solar cell (*left*) or on its rear face (*right*). In the latter case, the cell has a limited absorption range towards the high energy side. Optimally, the gap of the converter is twice that of the solar cell

is non trivial as well, if most photons emitted by the converter are to be harvested by the cell.

Finally, no materials are known with significant efficiencies in a range relevant for solar cells.

Multitemperature Generation (QE = 1)

Hot Carrier Solar Cells

The carriers generated in the absorber are not thermalized instantaneously with the network at temperature T_A, but form in a transitory way a hot gas of electrons and holes: their distribution corresponds to a temperature $T_H > T_A$. If these carriers can be collected quickly via selective energy levels (Fig. 15), the heat flow through the contacts is minimal and the kinetic energy conversion of hot gas into electrical potential energy is optimal [90]. Calculations of the limit of output give values very close to those obtained with a multijunction device containing an infinite number of cells, each one adapted to a fraction of the spectrum, and this for a system of a much simpler concept: it thus acts, to some extent, as the ultimate device of solar transformation energy. No cell with hot carriers was built yet; however, experiments showed that hot carriers' thermalization rates can be reduced under strong excitation in nanostructures to the point that conversion efficiencies above 50% under concentration are possible [13]. The efficiency is sensitive to the energy width of the contacts beyond some meV because the latter introduce a thermal loss by transfer of heat. But more than decreasing the thermalization rate, the practical realization of selective contacts is likely to be the delicate point in the fabrication of these devices.

At this stage, only thermalization rates have been measured both in bulk materials and in MQW. Those have been measured from time resolved PL as well as from CW techniques. They have yielded thermalization rates compatible with a significant gain under maximum concentration [49].

It has been shown also that reducing the thickness of the absorber is important to reduce thermalisation rates. Therefore a very efficient light confinement will be required. Thermalization rate reduction can also be achieved by phononic engineering, i.e., by preventing complete dissipation of the electron excess energy [12]. Finally, extraction of hot carrier may prove the most

Solar Cells: Very High Efficiencies Approaches. Figure 15
Energy band diagram of a hot carrier solar cell. Photons are absorbed in the absorber where electron-hole pairs are generated, forming a hot electron-hole gaz. Photogenerated carriers can be collected in electrodes, ideally using energy selective contacts

Solar Cells: Very High Efficiencies Approaches. Figure 16
Energy band diagram of a cesiated semiconductor photocathode and a metalic anode. Here, the energy of the emitted electron can be above the vacuum level. This is a configuration used in photodetectors (from Smestad 2005)

delicate challenge. There, a possible solution has recently been proposed to replace selective contacts by semiselective contacts [48].

Another mode of realization of the hot carrier solar cell is base on thermoionic conversion (Fig. 16), whereby hot carriers (or carriers from a hot cathode) are emitted in vacuum and collected at the anode.

There are numerous issues with this approach, on which a lot of work was carried out in the 50's [36], and namely, material stability at the high temperatures needed for significant thermoionic emission, creation of the space charge at large current. Recently, it was proposed to use semiconductor cathodes such as cesiated GaN, that could operate at much lower temperature [69]. This may enable to revisit the question.

TPV

In the thermophotovoltaïc configuration, solar energy heats a radiator at relatively high temperatures (>1,000 K typically). The energy radiated by the radiator is then converted by a photovoltaic cell whose gap is adapted to radiated energy. This system can be used to convert heat into electricity [22]. In the thermophotonic configuration [28], the radiator, an online polarized junction p–n, is what makes it possible to increase the quantity of radiation emitted. It is actually not so easy to find a selective emitter being effective at radiating the power in a relatively narrow band.

The thermal management of this device is particularly difficult, and, as the current density should be large, then it is also required to pay attention to possible Joule losses.

Rectennas

If the solar radiation is seen like an electromagnetic wave, it is in theory possible to collect it with an antenna and to rectify the induced current. Of course, one would need micron-scale antennas and especially high-speed diodes (> THz), beyond the state of current technology (Fig. 17).

Very important efficiencies were announced (70%) with the possibility of using molecular systems (at low prices thus). A company under contract with the US army would have started a few years ago (Lumeloid). Another company (ITN) under contract with the NREL explores the systems resulting from microelectronics (diodes MIM) and predicted outputs of

96% [6]. It is the Rectenna concept (network of antennas and rectifiers) illustrated below.

An effect (very weak) has been highlighted in experiments [53]. A deeper analysis raises some questions nevertheless: the antennas would function well with a monochromatic and coherent radiation, how would they perform with natural light? It thus seems that the estimates are to be strongly reexamined with the fall.

Solar Cells: Very High Efficiencies Approaches. Figure 17 SEM image of a network of antennas for the Rectenna concept [6]

It is impossible to rectify noise, but it is on the other hand it is possible to extract some energy from noise if this noise has a larger temperature than that of the diode. The limit of output for a system using a broad band antenna is 48% [74]. The problem of the antennas is well discussed by [14, 15].

Future Directions

Two well established paths to high efficiency have been identified: concentration and multijunctions. Both should make progress. For instance, advanced optical management, as implemented in the recent nanophotonic approaches are very promising and have a strong potential to contribute to further efficiency progress [2]. By increasing the energy density per unit volume, plasmonic and other nanophotonic approaches contribute to the concentration impact on efficiency. Multijunctions approaches will certainly flourish in the near term as many successful

Solar Cells: Very High Efficiencies Approaches. Table 1 Maximum theoretical performance expectancy (thermodynamic limit) of the various approaches. The possible gains are given for the range of concentration 1× to 46,000× (maximum of possible concentration). In *italics*, in the third column, the systems for which one expects a particularly important impact of solar concentration in real systems

Type of cell (ideal limits)	Range of output AM 1.5 to ×46,000	Remarks
Tandem N > 100	68–87%	Extremely complex
Hot carriers	67–86%	*Not shown in practice*
Impact ionizations (ts multiple E_g)	44–86%	Extremely complex, 5% in practice
Thermionic, thermal, TPV	54–85%	*In practice **23%** carried out*
Intermediate levels (N > 10)	62–85%	Extremely complex
N = 3 tandem	49–64%	In practice **39%** carried out
Upconversion	48–63%	*Small gain shown in practice*
Intermediate level (N = 1)	48–63%	*Not shown in practice*
N = 2 tandem	43–56%	In practice **32%** carried out
Down conversion	39–52%	Not shown in practice
Impact ionization (2 E_g)	38–52%	Small profit shown in practice
Rectennas	?–48%	*Not shown in practice*
Simple junction p–n	31–41%	In practice **28%** carried out

innovations on the processing (metamorphic and inverted metamorphic growth) and on the device architecture (integration of quantum dots and quantum wells) have been implemented. Yet it will become increasingly difficult to add more junctions, for an ever decreasing return, and at some point, one of the other concepts exposed above may take the relay to enable further efficiency increase (the potential of the various concepts is presented in Table 1).

Definition of the Subject

Assessments of the environmental impacts of energy-generation technologies are essential in evaluating their sustainability. Common metrics for evaluations of renewable energy systems include energy payback times greenhouse gas emissions, and toxic emissions in their cradle-to-grave life cycles. This chapter discusses the energy payback times (EPBTs) and environmental profiles of major commercial types of photovoltaics, i.e., monocrystalline silicon, multicrystalline silicon, and cadmium telluride, mounted on fixed-tilt ground-mount systems, and GaInP/GaInAs/Ge high-concentration solar tracking systems.

Introduction

Life cycle assessment (LCA) is a tool for measuring the indicators of environmental sustainability of products and technologies, including the generation of

Vasilis Fthenakis is a Senior Chemical Engineer, Senior Scientist, and the Head of the Photovoltaics Environmental Research Center at Brookhaven National Laboratory in a joint appointment with Columbia University where he is a Professor of Earth and Environmental Engineering and the Founder and Director of the Center for Life Cycle Analysis. He is the author of 250 publications, member of the Editorial Boards of Progress in Photovoltaics and the Journal of Loss Prevention. He is also a Fellow of the American Institute of Chemical Engineers, a Fellow of the International Energy Foundation, and member of several energy- and sustainability expert panels.

electricity through solar PV devices. Recent LCA studies show that PV technologies have very low environmental impacts compared to those of conventional electricity generation [1]. However, a broad review of the literature reveals several PV LCA studies with widely differing estimates. For example, the reported life cycle greenhouse gas (GHG) emissions of thin-film amorphous silicon (a-Si) PV systems range from 11- to 226-g CO_2-eq. per kWh of electricity produced [2]. Such divergence reflects different assumptions about key parameters, like product design, solar irradiation, performance ratio (PR), and lifetime. The estimates also deviate because of the different types of installation used, such as ground-mounts, rooftops, and façades. Most importantly, the assessments often are made from outdated information in the literature collected from antiquated PV systems, and are used for guiding policy analyses.

This chapter summarizes the results of PV life cycle analyses using as the main indicators energy payback times (EPBTs), greenhouse gas (GHG) emissions, and toxic emissions, based on actual data from the present-day commercial production of silicon-, thin-film-, and high-concentration photovoltaic systems. These indicators are crucial in assuring the public's acceptance of energy technologies because climate change arguably is the most significant threat facing our planet.

Material and Energy Inventories in the Life Cycle of Photovoltaics

The life cycle stages of photovoltaics involve (1) the production of raw materials, (2) their processing and purification, (3) the manufacture of solar cells, modules, and the balance of system (BOS) components, (4) the installation and operation of the systems, and, (5) their decommissioning, disposal, or recycling (Fig. 1). Typically, separate life cycle assessments (LCAs) are undertaken for the modules and the BOS components (inverters, transformers, mounting, supports, wiring), as the module's technologies evolve more rapidly and entail more options than do the BOS structures. The latter were considered herein for both ground-mount and rooftop installations; façade systems are not described as they are very much site specific. Processes in the life cycle stages of PV systems include the following:

1. Upstream Processes
   - Raw-material acquisition: e.g., mining the ores, extracting the fossil fuel, and growing trees
   - Materials production: e.g., metal smelting, purification, alloying, polymerization, wafer production)
   - Solar-cell production or thin-film deposition: e.g., wafer cutting, sputtering, chemical vapor deposition, vapor transport deposition

Solar Cells: Energy Payback Times and Environmental Issues. Figure 1
Flow of the life cycle stages, energy, materials, and wastes for PV systems

- Module production: e.g., contact formation, encapsulation, wiring, and assembly
- Module and BOS installation: e.g., installing module, inverter, and support structures

2. Operation and Maintenance: e.g., tracker operation, if applicable, rinsing if applicable, other scheduled maintenance, and office use for utility-scale plant
3. Downstream Processes
   - Decommissioning and disposal: demolition and transportation
   - Recycling: collection, disassembly, shredding, and material separation

Crystalline Si-PV Modules

A life cycle analysis starts with mining the raw materials (i.e., quartz sand for silicon PV; Zn- and Cu-ores for CdTe PV and the metals used in the balance of systems – BOS), and continues with their processing and purification (Fig. 2). The silica in the quartz sand is reduced in an arc furnace to metallurgical-grade silicon, which is purified into solar-grade polysilicon by either a silane (SiH_4)- or a trichlorosilane ($SiHCl_3$)-based process. The energy requirement for purification is the largest expense for making crystalline Si-PV modules, accounting for 45% of the primary energy used in fabricating multi-Si modules. Two technologies are

Solar Cells: Energy Payback Times and Environmental Issues. Figure 2
Detailed flow diagram for PV from the acquisition of raw material to its manufacturing stage

employed for producing polysilicon from silicon gases: the Siemens reactor method, and the fluidized bed reactor (FBR) method. In the former, which accounts for the majority (~90% in 2004) of solar-grade silicon production in the United States, silane or trichlorosilane is introduced into a thermal-decomposition reactor with high-temperature (~1,100–1,200°C) polysilicon rods [3, 4]. The silicon rods grow as silicon atoms from the gas phase deposited on them [3]. In 1987, MEMC Electronic Materials commercialized the FBR method on a small scale; recent developments show promise for scaling up production to meet the needs of the emerging solar industry. In this approach, granular polysilicon is produced by decomposing silane around seed particles in a mixture of silane/hydrogen fed into the reactor. This continuous production process offers inherent advantages over the Siemens batch-process, requiring lower energy consumption while enabling higher throughput. However, such advantages have not been quantified in life cycle analyses [5]. The life cycle inventory (LCI) data used in the studies reviewed here correspond to polysilicon production via the Siemens method, and were gathered in the European "Crystal Clear" project [3, 4]. Table 1 presents the aggregated life cycle inventories (LCIs), compiled from data from 11 European and a US plant [6–8]. Data on ribbon-silicon technologies are not presented herein, because these were found to be insufficiently documented. Detailed LCIs appear in a forthcoming IEA PVPS Task 12 report [9].

CdTe PV Modules

Fthenakis and Kim reported the LCI data for CdTe thin-film technology gleaned from the 2005 production data from First Solar's plants, Perrysburg, United States in 2005, and from Frankfurt-Oder, Germany data in 2008 [10, 11]. Held [12, 13] and Raugei [14, 15] used the same data in their independent investigations.

The life cycle inventories of the minor metals used in thin-film CdTe PVs (e.g., Cd and Te) are related closely to the production cycle of the respective base metals, Zn and Cu [16]. Cadmium is obtained from the waste streams in zinc smelting, mainly in the slimes from the Zn-electrolyte purification stages, and the particulates collected in baghouses, electrostatic precipitators, and cyclones in the thermal-oxidation units; thereafter, it is processed further and purified to the 99.999% purity required for synthesizing CdTe. Te is recovered after treating with dilute sulfuric acid the slimes produced during electrolytic copper refining; these slimes also contain Cu and other metals. After its cementation with copper, CuTe is leached out with caustic soda to produce a sodium-telluride solution that is used as the feed for Te and TeO_2. Additional leaching and vacuum-distillation produces Te- and TeO_2-powders of 99.999% purity required for

synthesizing pure CdTe. This same route is followed in generating solar-grade CdS, used as a window layer in CdTe PV. Both the CdTe- and CdS-layers are placed by vapor-transport deposition, based on subliming the powders and condensing the vapors on glass substrates. A stream of inert carrier gas guides the cloud of sublimed dense vapor to deposit the films on glass substrates at 500–600°C at a line speed of up to 8 ft/min [17], followed by depositing layers of metals. Thereafter, a series of scribing and heat treatments form interconnections and back contacts. Currently (4Q2010), First Solar produces CdTe PV modules with an efficiency of 11.6%.

Glass is the heaviest part of PV module, particularly in frameless CdTe modules where two panes of glass ensure their structural toughness. The double-glass design eliminates the need for an aluminum frame that accounts for a significant fraction of emissions from making silicon modules. The use of thin-film layers per unit area of thin-film CdTe, CIGS, and a-SiGe is minimal compared with silicon modules since the thickness of cell materials in the former is 1–3 μm compared with ~200 μm for the latter. Thin-film modules also require lesser amounts of consumables than do silicon modules, as fewer process steps are involved (Table 1).

CIGS PV Modules

Currently, CIGS PV are available in several major layer configurations depending on the substrate and encapsulation materials, including glass/glass, glass/polymer, and polymer/polymer. Reported module efficiencies range from 9.4% to 13.1%. In double-glass configuration, manufacturers offer frameless modules as the two glass sheets provide sufficient structural integrity.

The European Commission's project ECLIPSE (Environmental and Ecological Life Cycle Inventories for present and future Power Systems in Europe) was the first major research on the life cycle inventory of commercial CIGS PV. This project compiled life cycle inventories of emerging options for power generation, including PV, wind, and biomass. The PV technologies investigated were single- and multicrystalline silicon modules, and thin-film modules, such as amorphous silicon (a-Si), copper indium gallium diselenide (CIGS), and cadmium telluride (CdTe). This study reported the usage of mass of metals, glass, encapsulating polymer, and a frame, along with electricity requirement during manufacturing based on data from the literature [14].

Raugei et al. [15] collected the first life cycle inventory from an actual production line of CIGS PV, from a pilot-scale manufacturing process of Würth Solar, Germany [14]. The SENSE report [18] gave information on the production of CIGS solar modules by Würth Solar; Lazonovski and Held [19] summarize it. The sputtering of molybdenum aims at coating the "back contact." The substrates are structured by laser techniques. Targets of copper, indium, gallium, and selenium are coevaporated, and substrates carry the vapors under an inert-gas-flow process. A buffering layer of CdS (cadmium sulfide) is put on to the substrates by dip coating. The front electrode is deposited by the sputtering of zinc oxide, doped with Al_2O_3. Laser scribing follows the deposition of each layer. A functional test identifies the defective products. The addition of interconnects and front glass completes the module production. Section "Energy Payback Times and Greenhouse Gas Emissions: Results" shows the results of the SENSE report; however, the corresponding LCI data are not available.

Amorphous Si and Microcrystalline Silicon PV Modules

Uni-Solar, the biggest US producer of amorphous silicon PV products, manufactures triple junction a-SiGe photovoltaics on rolls of stainless steel that are cut to different sizes, varying from solar shingles to large laminates that follow the curvature of any roof. Keoleian and Lewis [20] modeled the environmental performance of a-Si BIPV roofing shingles. Since then, the company generated large laminates that are suitable for a variety of applications, while further developing their a-SiGe production line; recently, they announced their transition to TF-Si-based laminates. Kim and Fthenakis [21] conducted a life cycle analysis of replacing the intrinsic a-Si layer with a nano-crystalline Si layer. The investigators modeled a triple junction a-Si module, a-Si:H/a-SiGe:H/a-SiGe:H, while for nanotechnology, they assessed three prospective combinations of hybrid amorphous- and crystalline silicon cells (Fig. 3). The first configuration is a tandem

Solar Cells: Energy Payback Times and Environmental Issues. Figure 3

junction that consists of a-Si top layer and nc-Si bottom layer, i.e., a-Si:H/nc-Si:H; the second configuration is a triple junction with nc-Si as the bottom layer, i.e., a-Si:H/a-SiGe:H/nc-Si:H; and, lastly, a triple junction with two layers of nc-Si, i.e., a-Si:H/nc-Si:H/nc-Si:H. Oerlikon Solar developed a design called "Micromorph" that employs a glass substrate on which it laid out a TCO layer (transparent conductive oxide), followed by a-Si- and nc-Si-films. The life cycle energy demand of this design was compared with the above triple junction designs [21].

Major companies in producing thin-film silicon (TF-Si) equipment include Oerlikon and Applied Materials, both of which use NF_3, a potent greenhouse gas for cleaning the reactor in glass-based TF-Si; presently Uni-Solar does not do so. Fthenakis et al. [22] completed a comprehensive study on NF_3 emissions, from its production by Air Products and its use by Applied Materials.

High-Concentration Photovoltaics

High-concentration PV systems are equipped with GaInP/GaInAs/Ge triple junction cells produced by Spectrolab Inc. The cells have a nominal aperture-area efficiency of 37% under 500 kW/m^2, 25°C, and AM1.5

Solar Cells: Energy Payback Times and Environmental Issues. Table 2 Materials and energy inputs for processing 1,000 wafers, corresponding to 915 kWp[a] of GaInP/GaInAs/Ge terrestrial concentrator solar cell [2]

conditions. The semiconductor layers are grown on a germanium substrate via metal-organic vapor-phase epitaxy (MOVPE). Spectrolab Inc. provided the data on materials and energy input for the cell processing that are and summarized in Table 2. A 10% loss of inputs was assumed during the solar-cell production/dicing and assembly. The inventories are scaled for processing 1,000 wafers into 50,000 cells, corresponding to 915 kWp of capacity [23].

Fthenakis and Kim [24] reported an LCA of the Amonix 7700 high-concentration PV system employing these cells. This consists of seven concentrating module units, the MegaModules, mounted on a two-axis tracker. Sunlight is concentrated on to 7,560 focal spots at a rate of 500:1. This system uses multijunction GaInP/GaInAs/Ge cells, grown on a germanium substrate rated at 37% efficiency, under the test condition of 50 W/cm^2, 25°C, and AM1.5D conditions. With an aperture area of 267 m^2, the capacity of this unit corresponds to 53 kW$_p$ AC power.

Solar Cells: Energy Payback Times and Environmental Issues. Table 3 Material breakdown of the Amonix 7700

Sub module	Components	Materials	Mass (kg)	Fraction (%)
MegaModules	Cell	Semiconductor	0.2	0.001
	Frame	Steel	6,566	23.0
	Fresnel lenses	Acrylic	1,143	4.0

Other	Controller	Various	18	0.1
	Sensor	Various	1.4	0.005
	Anemometer	Various	0.1	0.0003

Table 3 shows the materials composition and mass balance of the Amonix 7700 system. While the measurements of the mass of manufactured parts were taken directly from the assembly line, the quantity of concrete used was calculated from the foundation's dimensions, i.e., 5.5 m deep, and 1.1 m diameter. The detailed material compositions of electrical parts, i.e., motor, transformer, and inverter, were estimated from Mason et al. [25]. The LCI includes the materials used in scheduled maintenance over an expected life time of 30 years; they include changing the hydraulic- and bearing-oils, cleaning the lens, and changing the air- and oil-filters. The MegaModules (36%) and tracker (58%) account for most of the components, while steel (75%), concrete (11%), and aluminum (11%) dominate the material usages.

Balance of System (BOS)

Photovoltaic modules are either rooftop- or ground-mounted. Silicon modules need an aluminum frame for structural robustness, while a second glass back-sheet performs the same function for thin-film CdTe PV. For a rooftop PV application, the BOS typically includes inverters, mounting structures, cables, and connectors. Large-scale ground-mounted PV installations require additional equipment and facilities, such as transformers for grid connections, office facilities, and, in some cases, concrete for installations.

De Wild-Scholten et al. [26] report the material inventories for two types of rooftop-mounting systems: on-roof mounting wherein the system is built on existing roofing material, and in-roof mounting where the modules replace the roof tiles. Table 4 shows the material life cycle inventory (LCI) of common rooftop-mounting systems, cabling, inverters, and transformers, including two sizes (500 W and 2,500 W) of small inverters adequate for rooftop PV designs.

Data on materials- and energy use for a ground-mounted BOS were obtained from the 5-MW_p PV plant at the Springerville, Arizona facility operated by Tucson Electric Power (TEP) (Table 5) [25]. The inverters are utility-scale models with a wide-open frame, allowing the facile replacement of failed parts. Thus, inverters and transformers are expected to last 30 years, with parts amounting to 10% of their total

Based on 12.2% rated efficiency for mc-Si module
[a]Xantrec PV-150 inverter type

photovoltaics-specific parameters are those agreed within the International Energy Agency (IEA) Task 12 [27]; they are summarized below:

Life expectancy
- Modules: 30 years
- Inverters: 15 years for small plants (residential PV); 30 years with 10% of replacement of parts every 10 year for large plants
- Structure: 30 years for rooftop- and façade-installations and 60 years for ground-mounted ones
- Cabling: 30 years

Performance ratio
- The performance ratio (PR) accounts for the losses from dc to ac conversion, thermal losses, and wire losses, and depends on the kind of installation. In general, the ratio increases with a decline in temperature build-up and monitoring the PV systems for early detection of defects; this means that well-ventilated and large-scale systems have a high performance ratio. A PR of 75% was assumed for rooftop and 80% for ground-mount utility-scale installations.

Degradation
- The degradation of the modules lowers efficiency over the life time. For mature module technologies, a linear degradation of 80% of the initial efficiency was assumed at the end of the 30 years life.

Energy Payback Time

The energy payback time (EPBT) is defined as the period required for a renewable energy system to generate the same amount of energy as that used by the system from cradle to grave. For a PV system, it is quantified as follows:

$$\text{Energy Payback Time(EPBT)} = \frac{E_{comp} + E_{man} + E_{inst} + E_{EOL}}{E_{a.gen.:} + E_{a.oper}}$$

where,

$E_{comp.}$: Primary-energy demand to manufacture the components (includes the energy to produce materials comprising each component)

E_{man}: Primary-energy demand to manufacture the modules (includes electricity as primary-energy equivalent)

$E_{inst.}$: Primary-energy demand to assemble and install the system

E_{EOL}: Primary-energy demand for end-of-life management

$E_{a.gen.}$: Annual electricity generation (primary-energy equivalent)

$E_{a.oper.}$: Annual energy demand for operation and maintenance (primary-energy equivalent)

Calculating the primary-energy equivalent requires knowing the country-specific, energy mixture used to generate electricity and produce materials. The annual electricity generation (E_{agen}) is represented as primary energy based on the efficiency of electricity conversion at the demand side. The electricity is converted to the primary-energy term by dividing it by the average conversion efficiency of 0.29 for the United States and 0.31 for Western Europe [28, 29].

Greenhouse Gas Emissions

Greenhouse gas (GHG) emissions during the life cycle stages of a PV system are estimated as equivalents of CO_2 using an integrated time-horizon of 100 years; the major emissions included in GHG emissions are CO_2 (GWP = 1), CH_4 (GWP = 23), N_2O (GWP = 296) and chlorofluorocarbons (GWP = 4,600–10,600) [30]. (Global Warming Potential is an indicator of the relative radiative effect of a substance compared to CO_2, integrated over a chosen time-horizon; the GWP_{100} corresponding to a 100 year horizon is used here.) Electricity- and fuel use during the production of the PV materials and modules are the main sources of the GHG emissions for PV cycles. Methods of generating the upstream electricity also play an important role in determining the total GHG emissions, as the higher the mixture of fossil fuels is in the grid, the higher are the GHG- and toxic- emissions. Thus, the GHG emission factor of the average US electricity grid is higher than that of the average Western European (UCTE) grid; that of China is higher than both of them. During 1999–2002, the US average CO_2 emissions inventory from electricity production and transmission was 676 g CO_2/kWh, while, in Germany, it was 539 g CO_2/kWh, and in China, it was 839 g CO_2/kWh [31]. These differences correspond to an estimated increase of 20% in the GHG emissions for producing modules and BOS components in China versus in the United States. Furthermore, transporting the modules and BOS components from China to either the United States or Europe could add an additional 15% to the GHG emissions.

Energy Payback Times and Greenhouse Gas Emissions: Results

EPBT

The latest (2010) estimates of the primary-energy used in the life cycle of complete rooftop Si-PV systems are 2,700 and 2,900 MJ/m^2, respectively, for multi-, and monocrystalline Si modules, down from 5,000 to 2,700 in 2006 [11]. The EPBT of these systems is 1.8 years for module efficiencies of 13.2% and 14% correspondingly, in rooftop installations under Southern European insolation of 1,700 kWh/m^2/year and a performance ratio (ratio between the dc-rated and actual ac electricity output) (PR) of 0.75 (Fig. 3). In these estimates, the BOS for rooftop application accounts for 0.3 years of EPBT, but there are different types of rooftop-mounting systems with different energy burdens.

For CdTe PV, the energy consumption is 850 MJ/m^2 and 970 MJ/m^2, correspondingly based on actual production from First Solar's plant in Frankfurt-Oder, Germany and Perrysburg, Ohio, United States. The energy burden at the US plant is higher than that in Germany because the former includes R&D and additional administrative functions. For insolation levels of 1,700 kWh/m^2/year, the EPBT for the European production is 0.8 year and for the US production is 0.9 year.

The EPBT decreases as the solar irradiation levels increases; for example, in Phoenix, Arizona, US Southwest, (latitude optimal irradiation of 2,370 kWh/m^2/year), the EPBTs of crystalline silicon- and cadmium telluride-PV in fixed-tilt ground-mount utility installations, respectively, are 1.3 and 0.6 years. At the same location, the two-axis Amonix HCPV would have an EPBT of 0.9 years (Table 6).

Greenhouse Gas Emissions

Brookhaven National Laboratory (BNL) in collaboration with the National Renewable Energy Laboratory (NREL) recently undertook a harmonization study of greenhouse estimates from the hundreds of reported

Solar Cells: Energy Payback Times and Environmental Issues. Table 6 Comparison of life cycle parameters and performances across PV technologies (normalized for Phoenix insolation)

PV system	Amonix HCPV, 7700 current	Multi c-Si ground-mount	Mono c-Si ground-mount[a]	CdTe ground-mount[b]

life cycle assessments. It consisted of systematically gathering nearly all publicly available life cycle assessments (LCAs) that referred to photovoltaics, screening them to ensure minimum standards of quality and relevance, and then reconciling several key performance characteristics (e.g., irradiation, system lifetime, module efficiency, and performance ratio) with standard values following the IEA Task 12 Guidelines [27].

Four crystalline Si-PV 400 studies were screened; before matching them, the median life cycle GHG emissions reported in the c-Si LCAs passing screens was 57 g CO_2e/kWh, with an interquartile range (IQR) of 44–73. After harmonization, the median estimate declined to 32–57 g CO_2e/kWh and IQR tightened to 27–35 [32]. The median GHG decreased because of higher irradiation, and a longer system lifetime. Standardizing irradiation and system lifetime were the most effective parameters reducing variability. The most valid LCAs for crystalline silicon modules are those based on data obtained from the CrystalClear Project. The GHG emissions of Si modules are ~29 g CO_2-eq./kWh range, for a rooftop application under Southern European insolation of 1,700 kWh/m^2/year, and a performance ratio (ratio between the dc-rated and actual ac electricity output) (PR) of 0.75 (Fig. 4). Notably, under these estimates, the BOS for rooftop applications accounts for ~5 g CO_2-eq./kWh of GHG emissions. These calculations were based on the electricity mixture for the current (2009) production of Si that is powered by hydroelectricity.

The harmonization process of thin-film photovoltaics involved 109 LCA studies [33]. As with the work

Solar Cells: Energy Payback Times and Environmental Issues. Figure 4
GHG emissions of PV systems: rooftop installed module with insolation =1,700 kWh/m^2/year and performance ratio = 0.75; European production

on c-Si activity, the initial screening eliminated abstracts, short conference papers, presentations without supporting documentation, and unrelated analyses; 90 studies passed this screening. In the primary screening, rigorous criteria were applied to assure the completeness of reporting, the validity of LCA methods, and the relevance to present times of the PV system studied. Additionally, it was determined whether the product is a commercial one, whether the production line still exists, and whether the study's core data is original or secondary. These screenings identified four studies as the best representations of the carbon footprint of the modern thin-film PV

technologies: Pacca et al. [34] for a-Si; Fthenakis et al. [1, 11] for CdTe; Raugei et al. [15, 35]; and SENSE for CIGS[18, 19]. The corresponding GHG emissions are 28, 17, 55, and 35 g CO_2-eq./kWh for irradiation levels of 1,700 kWh/m^2/year. The wide difference in the CIGS estimates highlights the need for more complete analyses of these technologies.

For assessing BOS, estimates were used of GHG emissions from rooftop systems, based on the Crystal Clear project [36, 37]; they correspond to 5 g CO_2-eq./kWh under 1,700 kWh of insolation, with 14% module efficiency, and performance ratio of 0.75. For ground-mounted BOS, data were employed corresponding to the Tucson Electric Power (TEP) power plant in Springerville, Arizona [25]. They are 5.4 g CO_2-eq./kWh, harmonized for the same conditions as the rooftop application. Emissions from the structural part of the BOS were adjusted according to the conversion efficiency of PV, whereas emissions from the inverter portion of the BOS that depend on power output were unchanged. Thin-film CdTe PV modules have no frames, and the same was assumed for CIGS modules. A triple junction a-Si module deposited on a stainless-steel substrate, manufactured by Uni-Solar, uses as a frame one with a very thin aluminum profile, specifically, 15 g of anodized extruded aluminum per m^2 of module, except for building-integrated applications [34]. Crystalline silicon modules employ a single glass sheet, and have an aluminum frame for structural stability, weighting ~3 kg per m^2 of module.

Both the as published- and harmonized-LCA results suggest that the carbon footprint of thin-film PV technologies fall significantly as production capacity increases, reflecting the technological advances in process- and device designs. For example, between 2005 and 2010, First Solar's annual production capacity of CdTe PV jumped from 25- to 1,100-MW_p, and, during the same period, the module efficiency of CdTe PV increased from 9% to 11.6% while the life cycle GHG estimates fell by ~30% [1, 11, 37]. Scaling up a CIGS PV prototype to a 15 MW_p commercial line for Würth Solar also likely will result in significant, but yet to be accurately determined, reductions in GHG emissions [15, 19].

Figure 5 compares GHG emissions from the life cycle of PV with those of conventional fuel-burning power plants, revealing the environmental advantage of using PV technologies. The majority of GHG emissions come from the operational stage for the coal-, natural gas-, and oil fuel cycles, while the material and device production accounts for nearly all the emissions for the PV cycles. With over 50% contributions, the GHG emissions from the electricity demand in the life cycle of PV are the most impactful input. Therefore, the LCA results strongly depend on the available electricity mix. The GHG emissions from the nuclear fuel cycle mainly are related to the fuel production, i.e., mining, milling, fabrication, conversion, and the enrichment of uranium fuel. The details of the US nuclear fuel cycle are described elsewhere [38].

Other comparisons between the life cycles of photovoltaics and conventional power generation cover land use [39] and water use [40]. Accounting for the land occupation in coal mining, it is shown that the life cycles of PV in the US-SW occupy about the same or less land, and orders of magnitude less water, on an electricity produced (GWh) basis, than the average coal-based power generation.

Toxic Gas Emissions

The emissions of toxic gases (e.g., SO_2, NO_x) and heavy metals (e.g., As, Cd, Hg, Cr, Ni, Pb) during the life cycle of a PV system are largely proportional to the amount of fossil fuel consumed during its various phases, in particular, processing and manufacturing PV materials. Figure 6 shows estimates of SO_2 and NO_x emissions. Heavy metals may be emitted directly from material processing and PV manufacturing, and indirectly from generating the energy used at both stages. For the most part, they originate as trace metals in the coal used.

Direct emissions of cadmium in the life cycle of CdTe PV were assessed in detail [41]. They total 0.016 g per GWh of PV-produced energy under an irradiation of 1,700 kWh/m^2/year (Table 7); this includes emissions during fires on rooftop residential systems, quantified in experiments at Brookhaven National Laboratory that simulated actual fires [42]. These experiments were designed to replicate average conditions, and the estimated emissions were calculated by accounting for US fire-statistics pointing to 1/10,000 houses catching fire over the course of a year in the United States where most houses have wood-frames, by assuming that all fires involve the roof. The indirect

[a]Ton of Cd produced

[b]Emissions are allocated between coproducts (Zn, Cd and other) based on mass and cost proportioning, according to ISO 14040 guidelines

[c]Energy produced assuming average Southern European insolation (i.e., 1,700 kWh/m^2/year), 9% electrical conversion efficiency, and a 30-year life for the modules

Cd emissions from electricity usage during the life cycle of CdTe PV modules (i.e., 0.24 g/GWh) are an order-of-magnitude greater than the direct ones (routine and accidental) (i.e., 0.016 g/GWh) [1, 10]. (Indirect emissions of heavy metals result mainly from the trace elements in coal and oil. According to the US Electric Power Research Institute's (EPRI's) data, under the best/optimized operational- and maintenance conditions, burning coal for electricity releases into the air between 2- and 7-g of Cd/GWh [43]. In addition, 140 g/GWh of Cd inevitably collects as fine dust in boilers, baghouses, and electrostatic precipitators (ESPs). Furthermore, a typical US coal-powered plant emits per GWh about 1,000 t of CO_2, 8 t of SO_2, 3 t of NO_x, and 0.4 t of particulates. The emissions of Cd from heavy oil burning power plants are 12–14 times higher than those from coal plants, even though heavy oil contains much less Cd than coal (~0.1 ppm); this is because these plants do not have particulate-control equipment [41].) Cadmium emissions from the electricity demand for each module were assigned, assuming that the life cycle electricity for the silicon and CdTe PV modules was supplied by the Union for the Coordination of Transmission of Energy's (European) grid. The complete life cycle atmospheric Cd emissions, estimated by adding those from the usage of electricity and fuel in manufacturing and producing materials for various PV modules and Balance of System (BOS), were compared with the emissions from other electricity-generating technologies (Fig. 7) [1]. Undoubtedly, displacing others with Cd PV markedly lowers the amount of Cd released into the air. Thus, every GWh of electricity generated by CdTe PV modules can prevent around 5 g of Cd air emissions if they are used instead of, or as a supplement to, the UCTE electricity grid. In addition, the direct emissions of Cd during the life cycle of CdTe PV are ten times lower than the indirect ones due to use of electricity and fuel in the same life cycle, and about 30 times less than those indirect emissions from crystalline photovoltaics. Furthermore, examining the indirect heavy metal emissions in the life cycle of the three silicon technologies discussed earlier revealed that, among the PV technologies, CdTe PV had the lowest energy burden and, consequently, the fewest heavy metal emissions (Fig. 8) [1]. Regardless of the particular PV technology, these emissions are extremely small compared to the emissions from the fossil fuel–based plants that PV will replace.

Ongoing LCA studies include evaluating replacing building materials with PV in building-integrated photovoltaics (BIPV) [44], and recycling of PV modules at the end of their useful life [45–47].

Conclusion

This chapter gives an overview of the life cycle environmental performance of photovoltaic (PV) technologies. Energy payback time (EPBT) is a basic metric of this performance: The lower the EPBT, that is the time it takes for a PV system to generate energy equal to the amount used in its production, the lower will be the emissions to the environment because emissions

mainly occur from using fossil fuel–based energy in producing materials, solar cells, modules, and systems. These emissions differ in different countries, depending on that country's mixture in the electricity grid, and the varying methods of material/fuel processing. Under average US and Southern European conditions (e.g., 1,700 kWh/m^2/year), the EPBT of crystalline Si-, and CdTe-rooftop PV systems were estimated respectively to be 1.8 and 0.8 years. Ground-mount installations entail a greater amount of BOS and, therefore, have a longer EPBT. Under US SW irradiation (e.g., Phoenix, AZ, 2,370 kWh/m^2/year at a fixed latitude tilt), the EPBT of ground-mount installations is estimated to be 1.3 years and 0.6 years, respectively, for crystalline silicon- and cadmium telluride-PV. At the same location, the EPBT of the Amonix 2-axis HCPV is assessed as 0.9 years.

The environmental impacts of the life cycle of photovoltaics as assessed by the common metrics of GHG emissions, toxic emissions, and heavy metal emissions are very small in comparison to those of the power generation technologies they replace.

R and D Needs

The EPBT and GHG emissions of photovoltaics will keep decreasing as the efficiencies of modules, inverters, and material utilization all increase. Such improvements and new products entering the market necessitate frequent updates of the environmental performance of PV.

New LCAs are needed for CIGS and a-Si as the published estimates are uncertain and outdated, correspondingly.

The environmental issues related to the installation and operation phases of very large (e.g., thousands of acres) PV facilities have not, so far, been addressed comprehensively in the literature; these need to be evaluated in a comparative context as PV are displacing fossil fuel life cycles.

Glossary

Absorptivity or absorptance (α) The fraction of the incoming radiation which is absorbed at a specified wavelength (absorptivity) or summed over a specified spectrum range (absorptance). Absorptivity and absorptance are dimensionless quantities.

Collector area: Aperture, absorber, and gross area Net area (of a flat surface) through which the collector receives solar radiation. The gross collector area, the aperture area, or the absorber area can be used. Usually, the performance of the collector is referred to the aperture area. For nonflat areas, a projected area is used for the aperture area, but the full surface area is taken for absorber areas.

Collector mean temperature (T_m) Defined, in operating terms, as the average value of the inlet and outlet temperatures of the collector (fluid) medium:

$$T_m = \frac{T_{outlet} + T_{inlet}}{2}.$$

Emissivity (ε) Ratio of energy radiated by a particular material at a certain temperature to energy radiated by a blackbody at the same temperature. For a true blackbody, $\varepsilon = 1$, while any real object would have $\varepsilon < 1$.

Emittance (M) Quantitative ability of a material to release radiative heat per area (W/m^2).

Evacuated tube collector (ETC) Solar collector with many parallel glass tubes each covering an individual long and slim absorber. The glass tubes maintain a vacuum insulation cavity around the absorber.

Flat plate collector (FPC) Solar collector with a large flat absorber. Optionally, a flat cover (covered flat plate collector) and conventional thermal insulation can be added to reduce thermal losses.

Heat pipe Heat transfer construction enabling heat transfer through (closed) convective mass flow. Usually, a critical fluid-gas material is used where gas rises when a fluid is heated below and flows down again when cooled at the top (liquid), thus transferring some sensible but also large amounts of latent heat. Very high heat transfer rates can be sustained through a single, small channel.

Incident angle modifier (IAM) Dependence of the collector efficiency on the angle between the solar beam radiation incident on a surface and the normal to the collector surface. With increasing incidence angle, reflections of the cover usually increase and the performance of the covered collector drops.

Operating temperature difference Difference between the collector mean temperature (T_m) and the ambient temperature (T_a). Usually, the collector performance curve is shown dependent on the operating temperature difference.

(Solar) Irradiance (G) Irradiated power density (in W/m^2) of (solar) radiation. An example is the solar constant, that is, the solar irradiance measured just outside the earth's atmosphere, which is roughly 1,361 W/m^2.

Spectral-selective coating Multilayer surface coating with high absorptivity in the wavelength range of solar radiation and low emissivity in the infrared thermal radiation range so that radiative thermal losses of the solar absorber are reduced.

Solar fraction (F_{sav}) Ratio of solar energy to total energy used by a heating system. Calculated from the auxiliary energy still needed when using solar energy, divided by the energy needed by a comparable reference system that does not use solar energy:

$$F_{sav} = 1 - \frac{Q_{aux}}{Q_{ref}}.$$

Solar spectrum AM 1.5 Typical spectral distribution of the solar radiation intensity on the earth resulting from transmission through an air mass of 1.5 times (AM 1.5) the thickness of the atmosphere of the earth, which corresponds with incoming solar radiation at an (solar zenith) angle of roughly 45° (to the vertical axis).

Definition of the Subject

The purpose of a solar thermal collector is to capture solar radiation, convert it into heat, and make the heat available, for example for use in a solar-heating or solar-cooling system. At the heart of the solar thermal collector is the absorber where the conversion from radiation into useful heat happens.

The simplest collector consists only of an absorber. But usually, the efficiency of the collector and the temperature of the heat produced are improved by reducing the temperature losses from the absorber by adding a collector housing or by increasing the intensity of the solar radiation with concentrating mirrors before it strikes the absorber. Concentrating solar collectors are used to produce medium- or high-temperature process heat above 100°C/212°F, to run thermal cooling machines, or to produce electricity by using steam generators. Non-concentrating solar thermal collectors are used for swimming pool heating, domestic hot water (DHW) heating, space heating, and heating of water for industrial and other processes and to run thermal cooling machines.

Engineered solar thermal systems were first used as far back as the nineteenth century (Fig. 1). In 1891, American Clarence Kemp received a patent for a solar heater device which combined the use of a black-colored water storage tank and the principle of the "hot box," a (wooden) insulated box with a glass front to capture and store solar radiation [1]. In the following decades, further design improvements were made. In 1909, William J. Bailey patented a new design. He reduced the heat losses by placing an insulated storage tank inside the house and exposed the solar collector to the sun outside. The two separate components were connected with thin pipes. At any time, little water was present in the collector; thus the collector heated the present water fast and to sufficiently high temperatures.

Solar Collectors, Non-concentrating. Figure 1
A bare-tank solar water heater used throughout rural America in the nineteenth century (John Perlin Solar Archives)

This design enabled the heated water to be stored overnight with reduced thermal losses and allowed the heated water to be used the next day.

Non-concentrating collectors are able to use direct (beam) solar radiation under various angles as well as diffuse radiation scattered by atmospheric influences. They do not need to track the sun's position and can be installed in a fixed orientation. In contrast, concentrating collectors can only use direct radiation and a very small fraction of the diffuse radiation available. Therefore, they need to be tracked to the sun's position.

Non-concentrating solar thermal collectors can reach temperatures of up to 250°C/482°F, but since the efficiency decreases with increasing operating temperature, they usually operate and deliver heat at acceptable efficiencies at temperatures up to 100°C/212°F, with special high-efficiency non-concentrating collectors delivering heat up to 150°C/302°F.

This document only discusses non-concentrating solar thermal collectors, here referred to only by "solar collectors" or "collectors."

Introduction

Heating of domestic water became simple and cheap using fossil fuels and interest in solar thermal heating disappeared, until the 1970s when the oil crises led to

a growing interest in alternative energy sources. The development of solar thermal systems boomed in most European countries in the 1970s but dropped again at the beginning of the 1980s due to quality problems and because fossil fuel prices dropped again. A relevant market for solar thermal systems remained only in Israel, Cyprus, and Greece due to the obligation to use solar thermal systems for hot water production (Israel) or a high inflation rate (Greece). In general, in these countries, cheap and simple solar thermal systems were used. The solar thermal markets in Austria and Germany grew again since the end of the 1980s due to growing environmental awareness, technical improvements, and subsidy programs. Other European countries followed this trend in the first decade of the twenty-first century, mainly stimulated by subsidy programs. Europe was the leading solar thermal market in the twentieth and at the beginning of the twenty-first century, but today, the world's largest solar thermal market is in China, with a global share of more than 80% (Fig. 2), where mainly simple thermosiphon solar thermal systems equipped with evacuated tubes for heating domestic hot water are used.

In Europe, growing concerns about climate change, scarcity of fossil energy sources, and the increasing dependency on imported fossil fuels have led to a fast-growing interest in local renewable energy options. About 50% of the final energy demand is caused by heating and cooling needs in European countries, and renewable heating and cooling technologies are seen as an important pillar of a sustainable energy system. Solar thermal is the renewable energy technology with the largest potential among them. According to the European Solar Thermal Technology Platform (ESTTP), solar thermal is able to cover 50% of the heat demand in Europe by 2030 [3].

In contrast, the huge solar thermal market in China is driven by the growing demand for comfort and by the fact that solar thermal is often the cheapest option to heat domestic hot water in China.

Solar Collectors, Non-concentrating. Figure 2
Share of the newly installed capacity (glazed and unglazed water and air collectors) by economic regions in 2009 [2].

Functioning of a Solar Collector

The task of solar collectors is to convert solar radiation into thermal energy and make it useable at a suitable temperature for a specific application with a high efficiency. In this chapter, the functionality of solar collectors is explained principally for flat plate collectors with a fluid as heat transfer medium, which are usually used in Europe for domestic hot water–heating and space-heating applications. The differences to other types of collectors are described in the following chapters.

The principal energy gain and loss mechanisms for a solar collector are shown in Fig. 3. Its power losses can be divided into optical losses (G_{loss}), occurring until absorption of the radiation, and thermal losses, occurring after absorption of the solar radiation. The power absorbed (useful thermal power $\dot{Q}_U$) is either removed by the heat transfer fluid as useable heat ($\dot{Q}_{\mathrm{out}}$) or is lost to the environment ($\dot{Q}_{loss}$). The radiation (G) and the thermal power ($\dot{Q} = \frac{Q}{\Delta t}$), with thermal energy Q and time difference Δt, are power units and describe an energy flow, which means energy per time unit.

To reduce thermal losses, most of the non-concentrating solar thermal collectors are insulated to the back and the side and covered with a transparent cover at the front. The transparent cover reduces the amount of solar radiation that reaches the absorber due to reflections of both sides of the cover as well as due to absorption of a small part of the radiation by the cover. The transmitted radiation reaches the absorber, where a small part is reflected and the remaining is absorbed and converted into thermal power. Using the share of radiation that is transmitted through the cover (transmittance τ_{cov}) and the share of radiation that is absorbed (absorption $\alpha_{\mathrm{abs}} = 1 -$ reflection), the thermal power ($\dot{Q}_{\mathrm{u}}$) converted from the absorbed radiation can be determined as follows:

$$\dot{Q}_U = \tau_{cov}\alpha_{abs}G_{tot}$$

The absorbed radiation heats up the absorber plate. If the heat transfer fluid, which is flowing through tubes connected on the back of the absorber, is cooler than the absorber, it is heated up and can remove the thermal power from the collector to the heat storage or a heat exchanger for direct usage. Therefore, the thermal energy must flow from every point of the absorber to the heat transfer fluid within the tubes. The thermal resistance between the point of absorption and the heat transfer fluid composed of the thermal resistance within the absorber sheet, at the connection point of the absorber sheet and the tube, within the tube material, and from the tube material to the fluid, is reducing the efficiency of the collector in addition. This is reflected by the collector efficiency factor F′ in the following equation:

$$\dot{Q}_{out} = F'\tau_{cov}\alpha_{abs}G_{tot} - \dot{Q}_{loss}$$

There are three physical mechanisms, which contribute to the heat losses ($\dot{Q}_{loss}$): conduction, convection, and (infrared) radiation, which are shown for a flat plate collector in Fig. 4.

Convection losses are reduced significantly by adding the casing, especially when operating in windy or cold surroundings. With the casing, convection is separated between convection between the heated absorber and the cover and the outside airflow (wind) over the cover.

Conduction losses mainly occur through the insulation material and through the transparent cover.

Solar Collectors, Non-concentrating. Figure 3
Principle energy flow in a solar thermal collector

Solar Collectors, Non-concentrating. Figure 4
Gain and loss mechanisms in a flat plate collector, with typical values relative to the incident solar radiation (in percentage of the incoming radiation)

Convection and conduction losses can be minimized by optimizing the distance between the absorber and the transparent cover [4]. The largest reduction of conduction and convection losses can be achieved by evacuating the gap between cover and absorber (i.e., by evacuated tube).

All thermal losses increase with increasing difference between the absorber temperature ($T_{absorber}$) and the ambient temperature (T_a). Since we are interested in the net useful thermal power ($\dot{Q}_{out}$), which is calculated from the temperature difference between inlet and outlet of the heat transfer fluid, the thermal losses are usually related to the difference between the mean collector temperature (T_m), defined as the average between the inlet and the outlet temperature of the heat transfer fluid, and the ambient temperature. Therefore, the thermal losses can be characterized quantitatively using the "operational" temperature difference ($T_m - T_a$) and a heat loss factor U_L:

$$\dot{Q}_{loss} = F' U_L (T_m - T_a)$$

The efficiency of a solar collector is defined as:

$$\eta = \frac{\dot{Q}_{out}}{G_{tot}}$$

Therefore, the linear efficiency curve of a solar collector can be described by [4]:

$$\eta = F'\tau\alpha - \frac{F' U_L (T_m - T_a)}{G}$$

with $\tau = \tau_{cov}$ (cover transmittance), $\alpha = \alpha_{abs}$ (absorber absorption), and $G = G_{tot}$ (solar irradiation).

Since the thermal losses are not exactly proportional to the operational temperature difference ($T_m - T_a$), often, the more precise quadratic collector efficiency curve is used:

$$\eta = \eta_0 - a_1 \frac{(T_m - T_a)}{G} - a_2 \frac{(T_m - T_a)^2}{G}$$

Therefore, the collector is typically characterized with the three parameters: maximum efficiency ($\eta_0 = F'\tau\alpha$), linear (a_1), and quadratic loss factor (a_2). The efficiency of a collector at a specific operating point is also called "instantaneous efficiency."

To compare the performance of solar collectors, their efficiency curves are usually presented as a function of the main influencing factors: the operational temperature difference ($T_m - T_a$) and the solar radiation (G) as shown in Fig. 5.

Solar Collectors, Non-concentrating. Figure 5
Typical efficiency curves of two covered and one noncovered flat plate collector (η = efficiency, T_m = mean collector temperature, T_a = ambient temperature, G = irradiation; the efficiency is related to the aperture area and is shown for an irradiation level of 1,000 W/m^2)

Figure 5 shows the efficiency curves of two covered flat plate collectors and one noncovered collector. A standard covered flat plate collector with a black-painted absorber shows typically a maximum efficiency of about 75%. Since the thermal losses increase with increasing operational temperature difference, the efficiency always curves downward starting from the maximum efficiency (η_0) where the temperature difference is zero. The highest collector temperature occurs when the heat transfer fluid is not circulating and the collector is in so-called stagnation mode; this is where the efficiency, and therefore net useful thermal power ($\dot{Q}_{out}$), is zero. In this case, the thermal losses are equal to the absorbed radiation. For a standard, covered, black-painted flat plate collector, the stagnation temperature is at around 150°C/302°F. An improved flat plate collector with a selective absorber coating and improved insulation, which is typically used in central Europe, shows a higher maximum efficiency of about 80% and lower loss coefficients a_1 and a_2. With improved heat loss reduction, the efficiency curve drops slower. A much higher stagnation temperature, of about 220°C/428°F, is achieved. In contrary, a noncovered swimming pool absorber has a slightly higher maximum efficiency point, since there are less radiation losses without a cover, but the efficiency curve drops much faster due to high-temperature-dependent losses (high values for loss coefficients a_1 and a_2) as a result, and the stagnation temperature is below 100°C/212°F.

To make efficiency curves comparable, two parameters must be stated: the referring collector area and the irradiation level. The relevant collector area must be referenced when presenting an efficiency curve since the total irradiation used in the efficiency is proportional to it. There are three options: the gross collector area, corresponding with the overall dimensions of the collector including the frame; the aperture area, through which the radiation can enter the collector; and the absorber area, which is the dimension of the absorber. The reference dimensions of collectors for the areas are shown in Fig. 6. The difference between the gross collector area and the absorber area is much smaller for a flat plate collector than for evacuated tube collectors.

The collector efficiency curve is usually shown as a function of $(T_m - T_a)/G$, which implies that the

Solar Collectors, Non-concentrating. Figure 6
Different dimensions of reference areas to calculate the efficiency of a flat plate collector

efficiency curve of a collector is always the same for the same value of $(T_m - T_a)/G$. But the quadratic efficiency equation shows an additional factor "G" in the quadratic term:

$$\eta = \eta_0 - a_1\left(\frac{T_m - T_a}{G}\right) - a_2 G\left(\frac{T_m - T_a}{G}\right)^2$$

This means that it is necessary to state for which irradiation the efficiency curve is shown as the efficiency for a given value of $(T_m - T_a)/G$ is similar only within a limited range of the irradiation (G). This second order effect is higher for larger values of $(T_m - T_a)/G$. According to the European standard EN 12975, the collector efficiency must be tested at irradiation values between 800 and 1,000 W/m^2 and the efficiency curve must be shown for the irradiation of 1,000 W/m^2.

To present the collector curve as a function of $(T_m - T_a)/G$ helps with understanding the efficiency dependency of the collector. Generally, with increased irradiation (G), the operation point on the x-axis moves to the left, toward higher efficiencies. However, with increasing irradiation, the mean temperature increases as well; therefore, the movement along the x-axes is smaller than the change in the value of 1/G. In the first order, the efficiency is proportional to the temperature difference $(T_m - T_a)$. The lower the ambient temperature (T_a) (a shift to the right), the lower is the efficiency of the collector. Therefore, in winter, the collector efficiency is not only lower due to lower irradiation values but also due to a larger operating temperature difference.

On the other hand, the lower the mean temperature (T_m) (a shift to the left), the higher the efficiency. This shows the importance of low inlet temperatures (T_{in}), since the mean temperature strongly depends on it $(T_m = \frac{1}{2}(T_{in} + T_{out}))$.

To calculate the operational efficiency of a collector means to identify the mean temperature (T_m), since the irradiation (G) and the ambient temperature (T_a) are given in a specific operational situation. To identify the mean temperature (T_m), it is helpful to see what is happening if the sun is shining on the collector. Then, the net useful thermal power $(\dot{Q}_{out})$ is increasing with the mean temperature for a given inlet temperature (T_{in}) as follows:

$$\dot{Q}_{out} = \dot{m}c(T_{out} - T_{in}) = 2\dot{m}c(T_m - T_{in})$$

Further factors of the equation are the mass flow $(\dot{m})$ and the specific heat capacity (c) of the heat transfer fluid.

On the other hand, with the increasing mean temperature (T_m), the thermal losses $(\dot{Q}_{loss})$ increase and the net useful thermal power $(\dot{Q}_{out})$ decreases:

$$\dot{Q}_{out} = G - G_{loss} - \dot{Q}_{loss}$$

Therefore, it can be followed that the resulting mean temperature (T_m) is the temperature for which both equations for the net thermal power $(\dot{Q}_{out})$ are true; this means:

$$2\dot{m}c(T_m - T_{in}) = G\left(\eta_0 - a_1\frac{(T_m - T_a)}{G} - a_2\frac{(T_m - T_a)^2}{G}\right)$$

This equation shows that the mean temperature (T_m) depends not only on the outside conditions of the collector, the irradiation (G), and the ambient temperature (T_a) but also on the inlet temperature (T_{in}), the mass flow $(\dot{m})$, and the thermal capacity (c) of the heat transfer fluid and, thus, on parameters which are provided by the solar thermal system.

The conclusion is that the efficiency curve of a solar collector with the collector parameters (η_0, a_1, a_2) is helpful to make solar collectors comparable. However, the operational efficiency of a solar collector at

a specific operation point not only depends on the outside conditions (G, T_a), but is also strongly influenced by some parameters of the solar thermal system (T_{in}, $\dot{m}$, c), which are influenced by the design and the operation mode of the system as well as the real load profile. This makes it very difficult to determine the mean temperature and therefore the efficiency of the collector at a specific time of operation. Since the outside conditions and the status of the solar system are changing continuously, the energy gains of a collector in a real solar system can only be calculated with a simulation program.

Construction of Solar Thermal Collectors

The central component of a solar collector is the absorber, which absorbs the solar radiation and converts it into thermal energy. The absorber is connected with a heat removal construction, which allows for the useful removal of heat by means of a heat transfer medium.

In order to reduce heat losses, the absorber can be embedded into a collector casing. For flat plate collectors, this includes a flat transparent cover and insulation material at the back and sides or, as is the case for evacuated tube collectors, the absorber can be covered entirely by a glass tube using vacuum as insulation.

Figure 7 shows cut sections of common collector constructions and their main components, from top to bottom: a noncovered (pool) collector mat, a covered flat plate collector, an air collector, and an evacuated tube collector (Sidney type). The header channels and manifolds of the evacuated tube collector, which collect the heated medium from the heat transfer tubes, are not shown. Many other variants exist especially of the evacuated tube collector type.

Absorber

The function of the absorber is to absorb the solar radiation, convert it into heat, and allow for the removal of the thermal energy for usage or storage. Different absorber constructions are used. In covered flat plate collectors, a thin metal absorber made from

Solar Collectors, Non-concentrating. Figure 7
Cut sections of common non-concentrating solar collectors showing their main components. From top to bottom: non-covered (pool) collector mat, covered liquid-heating flat plate collector ('sheet & tube'), covered air-heating collector (with air channels), evacuated tube collector (Sidney type)

a full sheet or a series of parallel fin-and-tube strips with heat removal tubing attached underneath is used.

Absorber Coating The solar radiation striking the absorber is either reflected or absorbed. Absorptivity (α) and reflectivity (ρ) are defined by:

$$\alpha = \frac{\textit{absorbed radiation}}{\textit{incident radiation}} = 1 - \rho$$

Absorptivity represents the share of solar energy that is converted into heat. The absorptivity of an ideal blackbody has the value 1. Solar absorbers are painted black or coated otherwise, for example, by applying a galvanic or a vacuum sputter process. Their absorptivity is usually between 0.9 and 0.95.

Like any object, the absorber emits infrared (thermal) radiation and exchanges this radiation with objects in its surroundings. The net radiative heat flow from the hot absorber to its surroundings, for example, a glass cover, increases with increasing temperature difference. The rate at which an object emits thermal radiation is characterized by the emissivity (ε) of its surface. The emissivity (ε) is defined as the ratio between the emissions of the object and the emissions of an ideal blackbody at the same temperature.

Ideally, a solar absorber should combine high absorptivity with low emissivity. Spectral-selective absorber coatings were developed which combine a high absorption in the solar spectrum with low emission in the infrared spectrum. Figure 8 shows the solar radiation spectrum, which occurs mainly at wavelengths between 0.3 and 2.5 μm, and the infrared emissions of a body with 100°C/212°F, which occurs mainly above 4 μm.

Figure 8 shows also the wavelength-dependent reflectivity of a high-quality spectral-selective absorber coating. Below 2 μm, its reflectivity is low and thus the absorptivity is high. In the infrared part of the spectrum above 4 μm, its reflectivity is high and therefore the emissivity is low.

The total absorptance (α) of good spectral-selective coatings is typically in the range of 0.90–0.95 for the AM 1.5 solar spectrum. This means that 90–95% of the radiation in this solar spectrum is absorbed. The emissivity (ε) of good spectral-selective coatings is between 0.05 and 0.10. This means that the absorber emits 5–10% of the infrared radiation of an ideal blackbody at the same temperature (e.g., 100°C/212°F in Fig. 8).

Solar Collectors, Non-concentrating. Figure 8
Intensity spectrum of solar radiation AM 1.5, emissivity of a blackbody radiation at 100°C/212°F and reflectivity of a selective absorber coating (all values normalized)

The spectral-selective coatings are made up of multiple layers containing compounds such as ceramic-metal structures (applied by PVD or physical vapor deposition), titanium-nitride-oxide (also applied by PVD), a selective lacquer (applied by coil coating), or black chrome (applied by electroplating). PVD usually leads to thin coatings which do not need to be removed before recycling; galvanic coatings (thickness 5–10 μm) and lacquer are thicker and one should consider removing these before recycling [5].

Absorber Material An absorber should be resistant to atmospheric conditions, since the collector is usually not hermetically sealed, and it must be resistant to it's stagnation temperature. Good collector performance requires high thermal conductance of the absorber; therefore, mainly well-conducting metals are used as absorber material.

In the past, mainly copper was used for absorbers due to its excellent heat conductivity (λ) (380–400 W/mK). Since the copper price increased dramatically and the ability of the collector manufacturers to reliably connect aluminum sheets with copper tubes has improved, the use of aluminum absorbers is steadily growing and has exceeded a 50% share in the European flat plate collector market. To compensate for the lower heat conductivity (200–240 W/mK), the aluminum absorber sheet typically has a thickness of 0.4 mm in comparison to copper absorber sheets with a typical thickness of 0.2 mm. To further decrease material costs, some manufacturers are also trying to replace copper heat removal pipes by improved and special corrosion-protected aluminum pipes. Stainless steel is very resistant against corrosion; however, it is very expensive and has a much lower heat conductivity (about 20 W/mK) and is therefore seldom used, for example, for noncovered stainless steel preheat absorbers.

Noncovered absorbers for swimming pool heating typically use cheaper polymer absorbers. These are usually made from EPDM (ethylene propylene diene monomer, an M-class rubber). Their heat conductivity is very low, only about 0.3 W/mK, but this is compensated for by placing many heat transfer channels closely side by side, which provides for short conduction distances between place of absorption and the heat transfer fluid. Polymer absorbers are extruded in one production step which includes the heat transfer fluid channels.

Some research is focused on reducing costs by replacing the metal sheet absorber by a polymer absorber for use in covered flat plate collectors. Since these collectors usually show a stagnation temperature between 200°C/392°F and 250°C/482°F, new heat-resistant polymers must be found or the stagnation temperature must be limited. Several experts, working together in Task 39 of the IEA Solar Heating and Cooling program, are working on new polymer concepts for solar absorbers [6].

Heat Removal Construction Only solar thermal energy, which is removed by the heat transfer medium, is usable. Therefore, the heat transfer medium must be in close contact with the absorber sheet. In the case of flat plate collectors, the heat removal construction mostly consists of pipes for a liquid heat transfer medium connected to the back of the absorber sheet or of air channels for air-heating collectors. In the case of evacuated tube collectors, the liquid sometimes flows through metal pipes as well, although in typical evacuated tube thermosiphon systems for the Chinese market, the heat transfer fluid is contained by the inner glass tube itself.

Up to now, in flat plate collectors, almost always copper heat removal tubes are used because of its good corrosion resistance. Copper is also used in other parts of the solar circuit, for example, the piping between the collector and the hot water storage tank and the heat exchanger in the tank. In Europe, the coated copper or aluminum absorber sheet and the heat removal tubes are usually welded together by laser or ultrasonically. In the past, the absorber sheet and pipes were connected by soldering, but due to the growing efficiency of the collectors, the stagnation temperature increased up to 250°C/482°F. Since this is a critical temperature for soldered absorbers, most of the European manufacturers of flat plate collectors abandoned this in their production method. But flat plate collectors with lower efficiency are still soldered. Rather seldom, the heat removal tubes are clamped to the absorber.

Another production method for absorbers is roll bonding, where two aluminum sheets are laminated by means of a high-pressure rolling process. The bonding of the two inner surfaces is a kind of autogenous weld formed by temperature (preheating) and pressure (rolling). The desired pattern of the flow channels are obtained by printing a nonwelding medium onto the

inside surface of one of the sheets. The nonwelded areas are expanded by applying pressurized air, thus forming the heat transfer fluid flow channels. These panel constructions have already been used for a long time for heat exchangers in refrigerators and freezers [7]. Roll bonding can be a cost-effective production method when volumes are large, and it has the advantage that it allows for very flexible designs for flow patterns to be created across the absorber surface. In the 1980s, solar equipment manufacturers experienced serious corrosion issues with aluminum components and roll bonding was no longer used. Nowadays, improvements have been made in understanding of and protection against corrosion so that some manufacturers are evaluating again the use of roll-bonding production methods.

The different ways to connect the heat transfer fluid tube to the absorber are shown in Fig. 9.

The coverage of the heat removal tubes across the absorber influences the efficiency of the collector directly through the collector efficiency factor F′ introduced in chapter "Functioning of a Solar Collector". With decreasing distance between the tubes, the collector efficiency factor F′ increases. At the same time, the number of tubes needed and thus production costs increase as well. Therefore, an optimum can be found. Currently, relative high values of F′, around 0.90–0.95, are common for most flat plate collectors in central Europe.

For fin-and-tube constructions, two patterns of the heat removal tubes are most common: harp and meander. In the harp pattern, the parallel tubes are connected at the bottom and the top with a header pipe. In the meander pattern, a single tube meanders across the absorber. Figure 10 shows the common patterns of the heat removal tubes for flat plate collectors. The advantage of the harp pattern is a lower hydraulic pressure drop, but there is a risk of unequal flow across the absorber. In the meander pattern, the fluid flows through a single tube, which leads to an equal flow across the absorber, but it has a higher pressure drop.

Solar Collectors, Non-concentrating. Figure 9
Cut sections of different constructions for flat plate absorber-tube connections. *Left*: absorber and tube laser or ultrasonically welded or soldered; *center*: roll-bonded sheets; *right*: pressed sheets

The main considerations for the heat transfer construction are good collector efficiency factor F′, low material usage, and low production costs. Influence factors are the required specific mass flow [kg/m^{2}h], the allowed pressure loss [Pa] which affects the pump power and energy needed, and an equal flow across each part of the collector. The heat removal of the absorber construction also has an influence on how several collectors can be connected to each other in a collector field.

Transparent Cover

Noncovered collectors cannot sustain acceptable efficiencies at absorber temperatures much above the ambient temperature. To reduce heat losses and allow higher temperatures, the absorber is usually built into a casing with a transparent cover at the top and insulation on the back and sides (for flat plate collectors) or encased in an evacuated glass tube (for evacuated tube collectors). The casing also provides protection to the absorber from environmental influences (e.g., rain, hail, dirt, and insects).

The cover should have high transmittance for solar radiation; else, it would reduce the radiation that reaches the absorber. The transmittance (τ) of a transparent cover is defined as the ratio between the transmitted and the incident radiation, measured at a right angle (90°) to the cover. It is reduced through reflections (ρ_{in} and ρ_{out}) on both sides of the cover and by absorption (α) within the cover material. Transmittance is thus determined by:

$$\begin{aligned} \textit{Transmittance}\ \tau &= \frac{\textit{transmitted radiation}}{\textit{incident radiation}} \\ &= 1 - \rho_{in} - \alpha - \rho_{out} \end{aligned}$$

The transmittance of "solar glass," with reduced iron content, is typically in the range of 0.89–0.91, compared to 0.84–0.88 for normal "float" glass. The higher iron content in float glass increases the

Solar Collectors, Non-concentrating. Figure 10
Various pattern of the heat removal tubes in flat plate collectors. From left to right: harp, double harp, and meander

absorption and typically causing the glass to appear green at the edges. For solar glass, transmittance can be enhanced to 0.94–0.96 by using antireflective (AR) coatings. The glass of vacuum tubes has similar values as solar glass, but no AR coatings are applied [8–10].

In a flat plate collector, heat losses through the cover can be further reduced by using a double cover. But adding another transparent cover also has the drawback of further reducing the radiation that reaches the absorber due to reflection and transmission losses by the second cover. With antireflective coatings becoming cheaper there is a growing interest in double covered flat plate collectors.

Flat plate collectors mainly use hardened (tempered or "safety") solar glass with common thicknesses of 3.2 or 4 mm. Hardened glass will shatter in many small pieces when damaged. This is a safety requirement reducing the danger caused by large pieces of falling glass. Hardened glass may not be accepted at recycling facilities because it melts at a higher temperature than normal bottle glass. Medium- and high-quality flat plate collectors use solar glass; only very simple and cheap collectors for regions with abundant insolation use float glass.

Evacuated tube collectors are usually made of blown borosilicate glass, which has a very low coefficient of expansion ($\sim 3 \times 10^{-6}/°C$ at 20°C). Just like tempered glass, borosilicate glass melts at a higher temperature than ordinary bottle glass and should thus not be recycled together with ordinary glass.

Other Collector Housing Elements

The collector needs to withstand augmented local wind and accumulated snow loads and must be tight to prevent water ingress. However, a fully hermetically sealed flat plate collector is very difficult to achieve due to high temperature differences between day and night, summer and winter, as well as absorber and ambient which leads to fluctuating positive and negative pressures in the collector. Therefore, flat plate collectors, in almost all cases, are allowed to "breathe."

The edge frame is the part of the absorber housing of flat plate collectors that not only allows the collector to be fixed to a supporting structure but also provides the necessary mechanical strength of the collector, maintains the distance between cover and absorber, and also protects the absorber and the insulation against environmental influences. The back is usually protected by a backing sheet, which protects the insulation from damaging, water ingress, and animal intrusion. The backing sheet is usually clamped, screwed, riveted, or glued to the frame. Figure 11 shows some different edge frame constructions for flat plate collectors.

The edge frame is usually made of extruded aluminum profiles, the back sheet of aluminum or sheet metal. Sometimes, the collector is integrated in the roof and replaces other roof cover material like tiles. The collector edge frame can also be made of wood when integrated into the roof or façade. The wood frame needs to be protected against environmental influences. This type of collector is mainly used in Austria. Sometimes, the collector housing parts are made from one piece; this could be from deep-drawn stainless steel sheet, from polycarbonate, or from fiberglass.

A main environmental consideration is the ability to replace, reuse, or recycle components. Frame, cover,

Solar Collectors, Non-concentrating. Figure 11
Different edge frame configurations for flat plate collectors

absorber, insulation, and backing sheet may be replaced, recycled, or even reused when they can easily be disassembled. From this point of view, components should thus not be irreplaceably connected to each other. The design of the edge frame plays a key role in facilitating this.

Insulation

In flat plate collectors, the edge and the back are usually insulated with mineral wool and sometimes with polyurethane foam. The insulation provides for low heat conductivity, temperature protection of some components, and in some cases, mechanical strength. The thickness of the back insulation depends on insulation material applied and is determined by the required efficiency of the collector. High-efficiency collectors for central Europe often use mineral wool with a thickness of 60 mm. In warmer climates, the insulation thickness is lower. Sometimes, different insulation materials are combined. Figure 12 shows a drawing of a cut section of a typical flat plate collector with side and back insulation.

Insulation material must be resistant against the stagnation temperature of the collector. For highly efficient flat plate collectors with stagnation temperatures reaching up to 250°C/482°F, special mineral wool is used to avoid outgassing of the binding agent in the mineral wool.

The tubes of evacuated tube collectors are sufficiently insulated by the vacuum and do not require additional insulation, but the manifold where the heat transfer tubes come together is usually insulated with mineral wool or polyurethane foam.

Reflector

Some evacuated tube collectors use a glossy sheet behind the tubes as a reflector. The sheet is usually corrugated showing a compound parabolic curved (CPC) profile, reflecting the radiation which passed between the tubes, back toward the absorber. This works as well as for beam as for diffuse radiation. The sheet, made from aluminum or from a polymer, has typically a polished and coated reflecting surface (Fig. 13).

Collector Types

Most of the solar thermal collectors used worldwide are evacuated tube collectors, since China has by far the largest solar thermal market and almost all collectors used in China are of the type evacuated tube. In contrast, about 90% of the solar collectors used in Europe are flat plate collectors. Up to now, almost all collectors use a liquid heat transfer medium, but air-heating collector use is increasing. Based on these characteristics, a general classification of non-concentrating solar thermal collectors is given in Fig. 14.

Solar Collectors, Non-concentrating. Figure 12
Cut section drawing of a typical flat plate collector with insulating material in the back and the side (*brown*)

Solar Collectors, Non-concentrating. Figure 13
Cut section drawing of an evacuated tube (Sidney tube type) collector with back reflector

Which type of collector "is best" depends on the intended application, location of use, required performance and operating temperatures, the typical ambient temperature range, the type of heating system in which the collector is to be integrated, as well as on mounting and aesthetic requirements, and of course the available budget.

However, the most important factor for choosing a solar collector type is the required operating temperature range. The application areas with their typical temperature ranges and the related collector types with their typical outlet temperatures are shown in Fig. 15.

Figure 16 shows a sample of efficiency curves of four different collector types. Typically, the efficiency at higher operating temperature differences increases for noncovered to covered flat plate collectors, without and with spectral-selective absorber coating, up to evacuated tube collectors.

In the following chapters, the most common collector types are described.

Noncovered Flat Plate Collectors

The simplest solar thermal collector consists only of an absorber with channels for the heat transfer fluid integrated into the absorber. The absorber is made of a dark material for high absorption of solar radiation. Since its heat losses increase strongly with the temperature difference between the absorber and the ambient, the usable operational temperature range of noncovered collectors is typically between 10 and 20 K above the ambient temperature. In the example shown in Fig. 16, the efficiency is 55% at an operating temperature difference of 10 K and an irradiation of 500 W/m^2 and of 20 K at 1,000 W/m^2. Therefore, noncovered solar collectors are used for swimming pool heating, preheating, and in combination with heat pumps only or as air-heating collectors for direct space-heating purposes.

The most common application of noncovered collectors is for pool heating. They are generally made of heavy-duty rubber or plastic treated with an ultraviolet (UV) light inhibitor to extend the life of the panels. The absorber consists either of many joined parallel polymer pipes or of extruded mats with channels made of

Solar Collectors, Non-concentrating. Figure 14
Breakdown of different types of non-concentrating solar thermal collectors

Solar Collectors, Non-concentrating. Figure 15
Indicative overview of solar thermal applications (based on temperature requirements) and a rough classification of solar thermal collector technologies, which can be used for these applications (based on typical output temperature of the collector)

a rubber compound. The joined pipes or mats are cut to length, and a manifold is added which connects the ends into a supply and removal header pipe.

Often, swimming pool water flows directly through the channels, picks up heat from the mat, and flows back into the pool. Figure 17 shows a drawing of a cut section of a typical polymer swimming pool absorber.

In some cases, noncovered collectors are made of stainless steel. Here, two sheets are bonded together, with the heat transfer fluid flowing between them through expanded or impressed structures (see Fig. 18).

Another type of noncovered metal absorber is from zinc plates, which is sometimes used as roof material. In this case, the heat removal pipes are connected on the back side of the zinc plates. Noncovered metal collectors can be used with the compression fluid of a heat pump which allows for lower operating temperatures. In some cases, the collector can function as the roof cover material at the same time.

Covered Liquid-Heating Flat-Plate Collectors

To reduce convection and radiative heat losses in covered flat plate collectors, the absorber is built into an insulated casing of metal, wood, or plastics to the back and the side and covered by a transparent cover at the top. The cover and the casing also provide protection to the absorber (coating) from environmental influences such as rain, hail, dirt, etc.

Flat-plate collectors are most common in Europe, with a market share of about 90%. Their main application area is domestic hot water–heating and space-heating support. The typical gross area of a flat plate collector is 2–2.5 m^2. Larger collectors of 6–12 m^2 are built as well, especially for use in large collector systems; however, a crane is needed for their installation.

In central and northern Europe, almost all flat plate collectors for domestic hot water and space heating have a spectral-selective coating of the absorber. Partly in southern Europe and mostly in northern Africa, absorbers are only painted (nonselective) black, since the irradiation and the ambient temperatures are higher. Therefore, the same solar gains can be achieved with a lower collector efficiency.

The distance between absorber and transparent cover must be optimized to significantly reduce the conductive and convective heat losses between absorber and cover. Since the absorber may curve due to the thermal expansion of the absorber cover, distance is typically a little more than the theoretical optimum, thus around 2 cm.

One option to further reduce heat losses through the cover of a flat plate collector is the use of a double cover. In a few cases, vacuum or low-pressure inert gas is maintained between the absorber and the transparent cover or in the entire collector because this is often not cost effective.

Evacuated Tube Collectors

Convection and conduction heat losses through the cover can very well be reduced without significantly affecting the transmission by using vacuum as insulation. For flat plate collectors, the air pressure differences cause large forces on the cover and casing, and to guarantee the tightness over 2 decades is a huge challenge. However, circular glass tubes are resistant to the pressure due to their edgeless shape, and for glass-glass-sealed tubes, the vacuum tightness is very high and reliable over time. The evacuated tube collector is therefore made-up of many parallel glass tubes each covering an absorber strip.

Two constructions of evacuated tube collectors are on the market. In single-walled tubes, the vacuum exists within the entire tube, and the absorber fin sits in the vacuum space; this construction requires a glass-metal seal to be able to effectively remove the heat; here, it is a challenge to maintain the vacuum reliable under varying operating conditions. In double-walled tubes, a second glass tube is located within the outer one and the vacuum exists only between these double walls; here, a glass-glass seal can be used since the heat removal construction is not placed in the vacuum space. In the so-called Sidney tube, the inner glass tube is selectively coated and works as the absorber. Within the inner glass tube, a metal heat removal construction is placed. There are different methods to transfer heat from the absorber in a single glass tube to the header of the collector. Either the heat transfer fluid flows through the pipe in the tube or a "heat pipe" is used.

A heat pipe is a sealed pipe filled with a liquid, for example, water or ethanol under low pressure, used for heat transfer. The heat of the absorber evaporates the liquid, which rises to the header where it condenses and thereby transferring the heat to the solar circuit. By using the latent heat of this evaporating/condensing mechanism, a large heat transfer capacity in a narrow connection is possible. For so-called dry connected heat pipes, the condenser is connected conductively with the metal of the heat transfer circuit; for wet connections, the condensing end is immersed into the fluid of the heat transfer circuit. The dry connection allows for easier replacement. The different types are shown in Fig. 19. At the top end of the collector, the so-called header, the heat removal fluid flows through the solar circuit (i.e., collector loop).

Because a glass cylinder may break, for example, due to hail or its vacuum may fail over time, the vacuum glass tubes are usually removable. Often, evacuated tubes contain a "barium getter" which helps to achieve high vacuum through barium reacting with common gasses. A resulting white area around the getter indicates when the vacuum is lost.

The evacuated tube collector's performance can be enhanced through the use of compound parabolic

Solar Collectors, Non-concentrating. Figure 19
Sectional views of the heat removal construction and the glass tubes of different types of evacuated tube collectors: left, single glass tube with coaxial heat removal tube; center, single glass tube with heat pipe; right, double glass tube (Sidney tube type) with vacuum between the two glass tubes

curved (CPC) reflectors located behind the tubes. This shaped mirror will reflect the solar radiation that passes between each evacuated tube back to the underside of the cylindrical absorber in the collector tubes (see Fig. 13).

Air-Heating Collectors

The use of air as heat transfer medium has some advantages: air does not cause problems when temperatures drop below 0°C/32°F or reach above 100°C/212°F; therefore, no frost nor overheat protection is needed. In addition, tightness requirements are much lower for air-heating collectors. On the other hand, other, less favorable, characteristics of air lead to some drawbacks: lower heat capacity and lower heat transfer capacity. Larger volume flows are needed for the same heat transfer due to the lower heat capacity of air; heat transfer from the absorber to the air is worse due to lower heat conductivity; in addition, storage of heated air is not practical. In general, air ducts are more voluminous than with liquid heat removal channels, but air collector constructions can also be simpler due to lower pressure and reduced leakage requirements.

The physical properties of air as a heat transfer medium differ significantly from those of water. In Table 1, the main relevant properties are listed.

Air-heating collector development focuses on improvements in the heat transfer construction due to its lower thermal capacity and the much lower heat transfer coefficient between absorber and air. An improved heat transfer coefficient can be achieved by increasing the surface area that is in direct contact with the air or by improving the contact itself, for example, by letting the air flow through holes in a sheet absorber, so-called perforated absorber.

Solar Collectors, Non-concentrating. Table 1 Comparison of relevant properties of air and water as heat transfer fluid at 25°C/77°F and 1 bar

Property	Units	Air	Water	Factor
Density	kg/m^3	1.18	998.20	~842
Specific heat capacity c (by weight)	kJ/(kgK)	1.00	4.18	~4
Specific heat capacity c (by volume)	kJ/(m^{3}K)	1.18	4,171.48	~3,500
Heat conductivity λ	W/mK	0.026	0.6	~23

Air as heat transfer medium allows for higher flexibility in the collector construction, such as the position of the absorber. Many different absorber geometries and collector flow designs can be realized. Figure 20 shows different absorber flow designs of air-heating collectors. Examples A1 to A3 and B1 to B3 are covered; A4 and B4 are noncovered constructions. Row "A" shows a perforated transparent cover or perforated absorbers, through which the air is passed and the transfer of heat is improved. A1 and A4 configurations take in fresh outside air through the perforated cover or absorber and are sometimes called "transpired." Row "B" shows covered and noncovered air collectors where the air flows between the cover and the absorber, behind the absorber, or on both sides of the absorber. A possible channel or fin structure attached to the absorber, which increases the absorber-air contact area, is not shown here.

The absorbers are usually made of metal (aluminum, copper, steel) or polymer sheets. Since they operate only at low temperatures, nonselective absorber coatings or just dark materials are used. Sometimes, a fleece made from polymers is used as absorber.

Air-heating collectors are most efficient and cost effective if the heated air is used directly for space heating within air-heating systems or other applications using hot air like drying of agricultural products or drying of sorption wheels of thermal cooling machines. The latter requires high operating temperatures.

Generally, two types of collector loop constructions can be distinguished: closed and open. For closed collector loops, the air is circulating through a closed solar air collector circuit and the heat produced is transferred to the point of usage by a heat exchanger. For open collector loop systems, the air coming in the collector is outside air, through holes in the perforated transparent cover or absorber or even a porous back, or a manifold supplying the outside air. The heated air in this "open loop" type is then used directly for heating or, for example, drying. Transpired collectors can only be part of open loop systems.

Covered air-heating collectors are mainly used in closed loop systems. These collectors are often installed

Solar Collectors, Non-concentrating. Figure 20
Different construction types of air-heating collectors

Solar Collectors, Non-concentrating. Figure 21
Schemes of solar air-heating collector systems: left, façade integrated; right, closed loop system with a covered flat plate collector

on the roof of a commercial building, and the heat is transferred into the ventilation system of the building by heat exchanger. The close loop can also be used to heat up water for use or storage. A scheme of such a system is shown in Fig. 21. For high-efficiency and high-temperature applications, a relatively new evacuated tube air-heating collector for temperatures up to 120°C has been developed [11].

Some air collector units operate independently of the electricity grid using a small PV panel integrated into the collector area to power a fan in the collector. These systems are often used in remote areas or to heat and ventilate holiday homes.

A common construction is to integrate air-heating collectors into the façade of a building. Covered as well as noncovered transpired air-heating collectors are used. The absorber then functions as the façade cover. Typically, the heated air is directly used for space heating in the rooms behind the façade, as shown in Fig. 21.

Noncovered air collectors can heat ventilation air and are used in places with high solar radiation during the heating season and buildings with large south-oriented façades. In North America, many solar air collector façades are realized for commercial, industrial, or institutional buildings.

The air-heating solar collector can also be used to heat a water store. However, with any air-water heat exchanger, there is a temperature drop between the supplying primary circuit and the receiving secondary circuit, and therefore, the efficiency is lower than in a liquid-heating collector system.

Another way to store the thermal energy from heated air is to lead it through a solid storage, for example, a pebble bed, which then stores the heat. Discharging is done in a similar way, again by leading air through the maze, picking up heat. Also, the structure of a building itself can be used as storage; in so-called hypocaust systems, the heated air is led through channels in walls, roofs, or floors, which store the heat. The heat is then slowly released through the building material into the building space.

An important difference to liquid-heating collectors is the strong dependency of the efficiency of solar air-heating collectors on the flow rate of the heat transfer medium. With increasing mass flow rate the efficiency of a air-heating collector increases, however, the pressure drop and therefore the electricity consumption of the blower significantly increases as well. It is thus important to take the electricity consumption of the blowers into account in the overall efficiency of the solar air-heating system.

Future Directions

Solar thermal collector technologies in the first phase are relatively mature. Well-performing, affordable, standard collectors for hot water heating are on the market with an efficiency close to the physical limits and which are durable and of high quality. However, since research and development in the solar thermal technology was rather small over the last decades, there is large room for further improvements for specific application areas and new concepts. The European Solar Thermal Technology Panel (ESTTP) within the European Technology Platform for Renewable Heating and Cooling (RHC-platform) showed in its vision of solar thermal technologies the potential for further developments [3]. For solar thermal collectors, the following developments are expected:

- Reduction of costs by introducing new materials and production methods into the collector
- Extension of the collector technology to other temperature ranges like process heat up to 250°C
- Integration of the collectors into the building envelope
- Adaptation of the collectors to the type of application, for example, cheaper collectors for lower temperature applications
- Development of multifunctional collectors like photovoltaic-thermal (PV-T) hybrid collectors for the production of electricity and thermal energy simultaneously on an irradiated area
- Further development of air-heating collectors for the optimization and integration into air-heating and ventilation systems
- Development of multifunctional solar thermal façade elements which can also be used for the refurbishment of existing buildings and which provide adjusted daylighting, insulation, ventilation, and active solar thermal collection
- Further development of large-area collectors to cover entire roofs of residential buildings and for very large collector fields for commercial applications and solar district-heating systems

Due to their potentially high efficiency, albeit at low temperature, non-concentrating solar thermal collectors are a very efficient path to harvesting the energy from the sun. The new challenge is to combine structural and functional building elements into one new construction as this often harbors contradicting requirements. New, cheaper materials and constructions are required, which are stagnation proof in addition to weather resistant over the long required lifetime of the element, to realize the high potential of solar thermal collectors.

Sun A so-called main-sequence star – converting He to H – with an age of 4.6 billion years. It rotates with a period of 27.28 days (seen from Earth) around its axis which is inclined to the ecliptic by 7.09° with an ascending node around 7–8 July.

Photosphere Visible surface of the Sun with $T_{\mathrm{eff}} \approx$ 6,050 K. It is defined as $\tau = 1$ at 500 nm which means that the "surface" at optical depth one is seen at the maximum of sensitivity of the human eye.

Solar cycle It is the main source of periodic solar variation and is observed by counting the number of sunspots visible on the Sun. It has an average period of about 11 years, and the last cycle with the number 23 started in August 1996 and ended November 2008.

Sunspot number The sunspot number R is defined as $R = k(10g + f)$ with the number of groups g, the number of spots f and a calibration factor k which accounts for instrumental and seeing condition of the observation. R is also a rough estimate of the total magnetic field penetrating the visible hemisphere.

Open magnetic field This is the radial component of the magnetic field in the heliosphere. It is measured at the orbit of Earth, that is at 1 AU (astronomical unit = 1.49598×10^{11} m) and varies with the solar cycle and on secular timescales.

Active region Complex of sunspots and faculae clustered together, starting at the beginning of a solar cycle at latitudes of about ±40° and migrating toward the equator during the cycle.

Ephemeral region Small bipolar region with sizes typically less than 20,000 km along their long axis, lifetimes of a few hours, and no sunspots. Their numbers vary only weakly with the solar cycle. Unlike active regions, ephemeral regions occur over the entire solar surface.

Sunspot Dark magnetic feature on the solar surface with diameters of 3,000–70,000 km. Spots larger than about 10,000 km have besides the dark umbra ($T_{\mathrm{eff}} \approx$ 4,240 K) a less dark penumbra ($T_{\mathrm{eff}} \approx$ 5,680 K). Normally, they exist in pairs with the leading (in the sense of rotation) spot having the opposite magnetic polarity of the cycle (after reversal of the polarity at solar maximum).

Facula Bright magnetic feature on the solar surface, mainly in active regions with similar sizes as sunspots. In contrast to sunspots with lifetimes of the order of a month, faculae can live for several rotations, even after the accompanying spot of the active complex has disappeared.

Plage The same as faculae but observed in the chromosphere in, e.g., CaK-II at 393.36 nm. They are larger in size because of the fan out of the magnetic field with height in the solar atmosphere, and can be used as a proxy for faculae with appropriate scaling.

Network Besides faculae and plages, there are small magnetic features summarized by the term network. They are mainly from decaying active region magnetic fields and are migrating poleward during a solar cycle.

Solar constant The amount of total solar energy of all wavelengths received by unit time and unit area at the mean Sun–Earth distance in the absence of the Earth's atmosphere. The term "Solar Constant" is somewhat misleading, because the irradiance is varying with the 11-year solar activity cycle and possibly over centennial timescales and hence "Total Solar Irradiance" or TSI is used. An irradiance of 1,365 W m^{-2} correspond to an effective temperature of the Sun of 5,777 K.

Definition of the Subject

Solar radiation received by the Earth, the "Solar Constant" is the main energy source and hence changes may influence the Earth's climate. Its value is between 1,361 and 1,365 W m^{-2}, a rather large range which reflects the uncertainty of the measurements in absolute terms. Decreases of total solar irradiance (TSI) over the solar-rotation timescale (27-day period) can be as large as 0.5% during the passage of large sunspots over the visible disk. The number of sunspots varies with the 11-year activity cycle and TSI shows an increase of about 0.1% or about 1.3 W m^{-2} during high activity, although more sunspots should result in lower TSI. This increase is due to faculae and network which enhance TSI. Although the absolute accuracy is the order or less than the cycle amplitude, these variations can be reliably observed due to the fact that the relative precision of the radiometers over an 11-year period is much higher, namely <0.001% or 0.5 mW m^{-2} per year. Reliable measurements from space started in November 1978 with the launch of NIMBUS7 and together with overlapping missions provide now a more than 30-year-long record for the study of solar variability. Understanding TSI variability is not only important for the advancement of solar physics, but also to understand its influence of the climate of Earth.

Introduction

The radiative output of the Sun was termed "Solar Constant" until the start of solar monitoring by satellite experiments revealed that it varies continuously and exhibits variations on all timescales – from minutes to decades, accessed thus far. Prior to the advent of space-based observations, astronomers and solar physicists argued that the radiative output of the Sun as a star changed in a substantial way only on evolutionary timescales of millions of years. While it was recognized that the occurrence of sunspots might change the irradiance at the Earth, their effect was considered negligible because they cover at most a few tenths of a percent of the visible solar disk. As well, the results of a half-century of ground-based program from 1902 to 1957 of the "Solar Constant" by the Smithsonian Institution inferred changes associated with the Sun's activity cycle for both the short-term decrease due to sunspots [1] and the 11-year cycle, shown as a positive correlation between sunspot numbers and the solar constant especially during the strong solar cycle 19 [2, 3]. However, the determined amplitudes were nearly an order of magnitude higher than evident from the space-based record shown in Fig. 1 and the results obviously were influenced by the highly varying terrestrial atmosphere. As a result, the view that the total radiative output was a constant quantity prevailed until the late 1970s, when space-based records became available. The first unequivocal evidence of solar irradiance variability on timescales from minutes to days and months was published by Willson et al. [4] from measurements by the ACRIM (Active Cavity Radiometer for Irradiance Monitoring) experiment on SMM (Solar Maximum Mission of NASA) during 1980 (see Fig. 1). The radiometer detected fluctuations that sometimes reached a few tenths of a percent and were associated with the movement of sunspots across the face of the solar disk visible at Earth as the Sun rotated on its axis. Such observations have been continued with overlapping missions until present and confirm TSI variability on all timescales. The understanding of these variations will not only improve the knowledge of the responsible mechanisms on the Sun, but also allow to reconstruct TSI back in time, possibly back to the Maunder Minimum in seventeenth century during which solar activity was very low with essentially no spots over a few decades and the temperature in Europe was low, it was the time of the so-called Little Ice Age.

Radiometry from Space, the Basis for Total Solar Irradiance Observations

Observations of TSI use radiometers which are based on the comparison of the absorbed solar radiation with electrical power; hence, they are called "Electrically

Solar Constant and Total Solar Irradiance Variations. Figure 1

Top panel: Compared are daily averaged values of the Sun's total irradiance from radiometers on different space platforms as published by the instrument teams since November 1978. Note that the VIRGO TSI is determined from both VIRGO radiometers (PMO6V and DIARAD), whereas the DIARAD TSI is only based on this one alone. *Bottom panel*: Sunspot number to illustrate the variability of solar activity for cycles 21, 22, and 23

Calibrated Radiometers" or ECR. Cavities replace a flat black-painted receiver to enhance the absorptivity of solar radiation to more than 99.99%. Moreover, the radiometers have a shutter which opens and closes periodically for a calibration of the heat flux meter without radiation. Most radiometers are operated in a so-called active mode which maintains the heat flux constant by controlling the electrical power in the receiver – hence the term "Active Cavity Radiometer" or ACR. The difference between the electrical power during closed and open phases determines the solar radiative power and, with the knowledge of the area of the precision aperture, the irradiance in W m^{-2}. A detailed description of the radiometers presently used in space and their operation can be found in Fröhlich [5].

Since late 1978 TSI measurements were made by different radiometers in space, namely HF (developed by Hickey and Frieden, Hoyt et al. [6]) within the Earth Radiation Budget (ERB) experiment on NIMBUS 7 (NOAA/NASA), ACRIM I [7] on SMM, ERBE (Earth Radiation Budget Experiment, Luther et al. [8]) on ERBS (Earth Radiation Budget Satellite) and other NOAA satellites, ACRIM II [9] on the UARS (Upper Atmosphere Research Satellite of NASA). SOVA (Solar Variability, Crommelynck et al. [10]) on EURECA (European Retrievable Carrier of ESA). VIRGO (Variability of Irradiance and Gravity Oscillations, Fröhlich et al. [11]) on SOHO, ACRIM III [12] on ACRIMSat and since 2003 TIM (Total Irradiance Monitor, Kopp and Lawrence [13]) on SORCE (Solar Radiation and Climate Experiment of NASA). Figure 1 shows these original time series, and it is clear that not only the absolute values are quite different, especially at the beginning of the period shown, but also early ACRIM I and HF data show differences which are due to the lack of a less exposed backup radiometer in the latter experiment. The ACRIM, VIRGO, and TIM experiments have such backup radiometers, which are only rarely exposed to the Sun, and by periodic comparison

with the operational one, the exposure-dependent degradation can be determined in situ.

Construction of a Composite of Total Solar Irradiance for the Last Three Solar Cycles

The time series from the HF, ACRIM I, II, and III, and VIRGO radiometers can be used for the construction of a TSI composite by shifting each series to a common level and merging them together. Presently, there are three composites available, the first one was presented in 1997 at the IAU General Assembly in Kyoto by Fröhlich and Lean [14] and is now called PMOD composite (for its construction see [15]). A few months later the ACRIM composite was published by Willson [16] which has been updated in 2003 by Willson and Mordvinov [17]. Somewhat later, a third composite, called IRMB, was presented by Dewitte et al. [18] (The composites are shown in Fig. 2 and available from: PMOD: http://www.pmodwrc.ch/pmod.php?topic=tsi/composite/SolarConstant, ACRIM: http://www.acrim.com/Data/%20Products.htm and IRMB: http://remotesensing.oma.be/en/3377935-TSI+composite.html). The ACRIM and IRMB composite use the data as published, whereas the PMOD composite introduces corrections of effects not considered in the original data analysis. Already in the early versions of the PMOD composite corrections for the HF degradation were applied [14, 19]. Similarly, the degradation of ACRIM I during first years was corrected for the effect of the rather short exposure time during the spin mode which was not taken into account in the original treatment by Willson and Hudson [20]. The corrected HF time series was used for the period before ACRIM started and during the spin mode of SMM and the corrected ACRIM I for the rest of time (1980 and 1984–1989) as basis for the composite of Fröhlich and Lean [19]. Fröhlich [15] included a further correction

Solar Constant and Total Solar Irradiance Variations. Figure 2
Shown are the three composites: (**a**) PMOD [14, 15], (**b**) ACRIM [16, 17], and (**c**) IRMB [18]

of ACRIM I for the early increase which was first observed in the PMO6-V measurements of VIRGO/SOHO and seems to be an inherent effect of most classical radiometers. Moreover, the substantially lower exposure time during the spin mode operation of SMM 1981–1984 imposed to take the effective dose into account which changes the rate of degradation substantially (see Figs. 3 and 4 of [15]). During the first 15 months of HF, no other radiometer is available as reference and a proxy model was used. This is the only period when a model is involved as reference. It is, however, calibrated to the corrected ACRIM I data over the period from 1980 to 1988 and is thus quite reliable for the period of a few years before 1980. For HF, all glitches throughout the mission are removed first and then the corrections for the early increase, the degradation and the long-term sensitivity increase were determined over the full period from November 1978 until January 1993, which yields an internally consistent time series (see Figs. 6 and 7 of [15]). In a last step, the absolute value of the PMOD composite is shifted to represent the SARR reference (SARR: Space Absolute Radiometric Reference as defined by Crommelynck et al. [21]).

Another problem for the composite constructions is how to bridge the so-called ACRIM gap between the end of ACRIM I and the start of ACRIM II (June 1989 to October 1991). During this period, daily values from HF and some 70 data points from ERBE with a sampling every 14 days are available. Already Lee III et al. [22] revealed two slips in the HF data resulting in a total change of -0.68 W m^{-2} over this period which was confirmed by comparison with a model derived from solar disk observations by the San Fernando group [23]. Fröhlich [24] re-analyzed this period and the overall change was again confirmed, but with a slightly different value of -0.58 W m^{-2}. Such changes no longer need to be corrected individually, because the HF time series, consistently corrected over the full period, can now be used directly for bridging the ACRIM gap.

Solar Constant and Total Solar Irradiance Variations. Figure 3

Shown are comparison of the three composites with the 18-year record of ERBS from 1985 to 2003: (**a**) PMOD [14, 15], (**b**) ACRIM [16, 17], and (**c**) IRMB [18]. The *yellow line* in (**a**) is the result of the linear fit to the difference over solar cycle 23

Solar Constant and Total Solar Irradiance Variations. Figure 4
Daily TSI of the PMOD composite (updated until end of March 2010 Version 41_62_1003a) and extrapolated with a proxy model back to 1976. The amplitudes of the three cycles decrease first and then increase again. The two *horizontal lines* indicate the value of the minima in 1986 and 2008, respectively. Note the low value of the 2008/2009 minimum, which is 0.22 W m^{-2} lower than the previous one, or 25% in terms of the mean cycle amplitude

The ERBE data set covers the period from 1985 to 2003 and more specifically the controversial time of the ACRIM gap. Although the record is quite noisy – mainly because of a low rate of sampling every 14 days – it can be used to illustrate the differences between the three composites as shown in Fig. 3. The ACRIM composite neglects the corrections of the HF during the ACRIM gap and thus shows a significant upward trend of TSI between 1985 and 1995 [16, 17, 25]. The IRMB composite traces ACRIM II to I via ERBE which results in an insignificant difference between the two minima in 1985 and 1995 similar to the PMOD composite. However, the IRMB time series during the ACRIM gap shows a strange variation which comes from the fact that it is normalized to the average of ERBE and HF, both referred to SARR. During the period of SOHO the IRMB composite is based on DIARAD data alone, which means that it is corrected for degradation by comparison with its backup, but misses the effect of non-exposure-dependent sensitivity increase. This latter effect can only be determined by comparison with another radiometer – in the case of VIRGO with PMO6-V – and its omission is the main reason for the increase of TSI during solar cycle 23 in contrast to the PMOD and ACRIM composites (see also Fig. 3). The deviation from ERBE can be fitted with an exponential function similar to the one which is used in the evaluation of the VIRGO data [26]. Furthermore, both the ACRIM and IRMB composite use the original data for the early part of the NIMBUS-7 mission which is – as explained above – strongly influenced by instrumental changes and is not representing solar variability.

Recently Scafetta and Willson [25], Scafetta [27] insinuated again that the PMOD composite is incorrect, because the corrections applied to the original ACRIM I and HF time series have no basis at all and are only applied to get agreement with a proxy model originally proposed by Foukal and Lean [28, 29]. As explained in detail in Fröhlich [15] and summarized above, the corrections are based on an improved understanding of the long-term behavior of radiometers in space, the results of which were not available to the teams evaluating ACRIM and HF. This was made possible by the detailed analysis of the almost 14-year-long solar irradiance record from the two VIRGO radiometers (PMO6V and DIARAD) on a thermally very quiet spacecraft SOHO (see, e.g., [26], and references therein). Besides the excellent agreement with the ERBE record, the PMOD composite agrees also much

better with proxy (e.g., [30, 31]) and other models Wenzler [32], Wenzler et al. [33], Krivova et al. [34], which demonstrates the consistency of the applied corrections. Thus, the PMOD composite is a reliable representation of TSI back to November 1978. From the experience gained by extrapolating ACRIM I back to the beginning of HF, the PMOD composite can be further extended back to the beginning of 1976 in order to cover cycle 21 from its minimum as shown in Fig. 4.

What is the Origin of the Variability of Solar Irradiance?

Figure 4 shows clearly that the TSI is variable on all timescales from days to decades. There are obvious changes on the solar-rotation (27-day) timescale during the passage of active regions with dips due to sunspots and rises due to faculae. Moreover, there is also a modulation with the 11-year period which may change in amplitude from cycle to cycle. The fact that TSI is higher during high activity contradicts the conjecture that more sunspots should make a darker Sun, but it supports the solar-terrestrial relationship that low TSI may lower the Earth's temperature as during the little ice age in Europe in the seventeenth century when the Sun showed very low activity with essentially no visible sunspots, a coincidence first noted by Eddy [35], who called this "Grand Minimum" Maunder Minimum. During the most recent cycle, the number of sunspots was less than during the two cycles before (see lower panel of Fig. 1) and there were even periods with essentially no spots which made the TSI amplitude during this cycle of the same order as during the ones before. The amplitude is defined here as an equivalent of a sine square (twice the average between the minima of the considered quantity). This may not ideally represent the detailed behavior of a solar cycle, which shows a much faster increase during the ascending phase compared to the rather slow decrease during the descending phase (see, e.g., Fig. 4). Besides the fact that this definition can be applied to any other quantity considered, it is for TSI relevant for the solar-terrestrial influence on the global climate with its rather long response time. Also an independent definition of the "time of minimum" is needed and the first appearance of an important sunspot group of the new cycle (at high latitude and of opposite polarity) is used. This method is illustrated by the butterfly diagram of PSI shown on Fig. 8, and the dates of the last four minima are 10 October 1976, 19 September 1986, 21 August 1996, and 29 November 2008.

Solar activity is driven by the magnetic fields produced periodically by a dynamo at the base of the convection zone at about 0.71 $R_\odot$ (for a review see, e.g., [36], and references therein). Magnetic fields threading the visible solar surface, the photosphere, produce features like sunspots and faculae related to active regions and bright network in and outside active regions. Figure 5 shows time series for solar cycles 20–23 of typical measures of solar activity. The sunspot number (SSN, Fig. 5a) is certainly the most widely used index mainly because it is available since the seventeenth century, but also because its cycle amplitude represents a measure for the varying amount of bipolar regions reaching the surface and hence the strength of solar activity during a cycle. The next parameter is the solar radio flux at 10.7 cm (F10.7, Fig. 5b) which is an absolute physical measurement available since 1947 (solar flux units $\equiv 10^{-22}$ W m^{-2} Hz^{-1}) which similar to the SSN represents a measure of the strength of solar activity. Figure 5c shows daily values of the Ly-α composite (starting with the measurements by AE-E from Woods et al. [37]) which is representative to the changes in solar chromosphere due to the magnetic fields on the surface. A similar behavior shows the CaII K and MgII indices (Fig. 5d, e) which also represent changes of the chromosphere due to the surface magnetism. None of these quantities show a significant decrease during the recent minimum as TSI. The observed trends between minima are at least a factor of 5–6 smaller than for TSI, summarized in Table 1.

For SSN, such a behavior is expected as the number cannot be negative, but all the other parameters of Fig. 5 have no lower limit of their values and thus could show a similar change as TSI. For F10.7, there is no significant change of the values at minima back to the start of the measurements in 1947. The CaII K index deduced from the Mt Wilson and Kodaikanal observations [39] back to around 1910 shows also no change in the minima to within ±4%. As the chromospheric indices are highly correlated with the UV and EUV irradiance and as shown by the Ly-record, secular changes of the spectral irradiance below about 300 nm

Solar Constant and Total Solar Irradiance Variations. Figure 5

Daily values of the time series of (**a**) SSN, (**b**) F10.7, (**c**) Ly-α irradiance, (**d**) Call K, and (**e**) MgII indices. The values indicated at solar minima (above the *vertical lines*) are the percent changes relative to the amplitude of cycle 22 and normalized to the value between cycles 21 and 22 indicated by the *horizontal blue line*. In contrast to TSI of Fig. 4, none of these records show the large decrease during the present minimum

are hence unlikely. All these observations show that the chromospheric temperatures during minima and hence the "quiet" magnetic Sun do not seem to change on secular timescales (see also [40]). This observation contradicts the assumption that the long-term changes of solar irradiance – spectral or total – are also caused by the same mechanism as the intra-cycle variation, namely by manifestations of the surface magnetic fields, that is sunspots, faculae and network, including ephemeral regions for a description (see, e.g., [41]).

As shown in Fig. 6 and Table 1, the only parameter that does exhibit inter-cycle changes similar to TSI is the open magnetic field. B_R, as observed at 1 AU by satellites since the 1960s (Fig. 6b). B_R is determined by taking the absolute value of the daily mean of B_X from the OMNI2 dataset (available from ftp://nssdcftp.gsfc.nasa.gov/spacecraft_data/omni/omni_m_daily.dat). Recently, Lockwood et al. [42, 43] have shown that a kinematic correction is needed to determine the open field of the Sun at the source region (at 2.5 $R_\odot$)

Solar Constant and Total Solar Irradiance Variations. Table 1 Cycle amplitudes and relative changes of minima in percent of the amplitude during cycle 22. The amplitudes are equivalent sine-squared with the trend during each cycle removed. The units are: TSI (W m^{-2}), the open field at 1 AU B_R (nT), SSN (number), F10.7 (sfu $\equiv 10^{-22}$ W m^{-2} Hz^{-1}), Ly-α (mW m^{-2}), CaII K and MgII indices (core-to-wing ratio). Updated from Fröhlich [38]

Parameter	Cycle 20	Cycle 21	Cycle 22	Cycle 23
Corrected cycle amplitude				
TSI	...	0.9244	0.8489	0.8427
B_R	...	1.361	1.482	1.161

F10.7	76.7	125.5	121.3	94.3
Ly-α	...	3.48	3.15	2.63
Call K	...	0.01270	0.00992	0.00810
MgII	...	0.0175	0.0151	0.0137
Change of minima over each cycle in percent				
TSI	...	6.0	−12.9	**−25.0**
B_R	...	5.0	−17.4	**−45.8**
SSN	0.8	1.0	−4.7	−4.3
F10.7	0.8	−1.6	0.1	−4.0
Ly-α	...	4.3	−7.3	−3.4
Call K	...	−1.6	−2.7	−1.5
MgII	...	0.3	1.8	−2.8

from the measurements at 1 AU. This correction, however, is not needed because B_R is more directly related to the interplanetary field (IMF) than the true open field and the IMF is what can be inferred from, e.g., the concentration of cosmogenic isotopes in ice cores produced by the galactic cosmic rays (GCR) or from magnetic measurements on Earth like the aa index. B_R has an intra-cycle variation quite different from TSI, because B_R changes sign around the maximum of the cycle (during periods of the reddish areas in Fig. 6b), and since the northern and southern hemisphere may change at different times, it is a prolonged period during which the behavior of the B_R variability is dominated by this reversal. This reversal happens during each cycle and produces the 22-year magnetic Hale cycle with the solar polar field having the same polarity as Earth's field. B_R during minima is mainly determined by polar field of the Sun and thus is more representative of the strength of activity during the solar cycle before and after than to the amount of surface magnetism which is due the non-axisymmetric fields.

Figure 6c shows the correlation between TSI and B_R as determined by linear regression. It is interesting that the line is very close to the points – much closer than one would expect from the error bars. This is also true for the point of the 1976 minimum, which is not used in the regression, indicating that its value – although based on a proxy model – is indeed quite reliable. The result of this correlation can be now used to calculate TSI at minima whenever B_R is known. An example of such a reconstruction of TSI during the Holocene is based on the record of the cosmogenic isotope ^{10}Be [44]. It is important to note that this correlation does not mean a direct physical relationship between TSI and B_R. As already suggested by Tapping et al. [45] and Fröhlich [38], the long-term trend may be due to global temperature change of the Sun with a magnitude related to the strength of the activity and hence to B_R

Solar Constant and Total Solar Irradiance Variations. Figure 6

Comparison of TSI and the open solar magnetic field. (**a**) Daily values of TSI (as Fig. 1) and (**b**) those of the open magnetic field B_R at 1 AU. The correlation between the minimum values of TSI and those of B_R (*blue points* and the *blue line*) is shown on (**c**). The *green point* is the extrapolated value not used in the regression. The error bars are from a detailed analysis as described in Fröhlich [38] and the errors of regression coefficients include these uncertainties, and hence are quite large

during minima. The temperature change needed to explain the difference between the last two minims is of the order of 0.25 K.

Extension of the Three-Component Proxy Model for Total Solar Irradiance

Proxy models of TSI are based on daily indices representing the darkening of sunspots and the brightening by faculae and network as illustrated in Fig. 7. A two-component model uses information on sunspots, ΔS_S from daily observations of their position and area, and one index for the brightening features ΔS_F, from, e.g., Mgll index. A three-component model uses two different indices for the brightening: ΔS_F and ΔS_N (for a review, see, e.g., [30], and references therein). But, as all three components do not show substantial changes between minima, a fourth component is needed to model the trends of TSI between the minima as already shown by Fröhlich [31]. The fourth

Solar Constant and Total Solar Irradiance Variations. Figure 7
(**a**) Sunspots and faculae in active regions (a, b), and network (c) imaged in the chromospheric Call K line where faculae and network are enhanced over their contrast in broad-band light and seen as so-called plages and bright network (Image taken by the National Solar Observatory on 28 August 1988). (**b**) A detailed image of the active region on the left limb as seen in the g-band (430.5 nm). The granules, covering most of the area, are the convective flows transporting the energy from the interior which contribute the steady component of the solar radiation. The magnetic features in an active region are the sunspots with the dark umbra and somewhat brighter penumbra and the faculae which are a dense carpet of bright points. (Image taken with the Swedish 1-m Solar Telescope by Dan Kiselman on 29 June 2003)

component can now be constructed from the values of B_R at the minima, connected by linear trends and providing ΔS_T. Since sunspots and faculae typically occur on the Sun together, a competition of their relative strengths determines the short-term solar irradiance variability. The solar cycle amplitude seems to be determined by magnetic features with smaller sizes than sunspots and faculae and distributed all over the Sun as network and the small bipolar ephemeral regions (see, e.g., [46]). The part coming from the latter are in the following included in what is called network. So, the four-component proxy model of TSI can be constructed as

$$S(t) = S_Q + a_F P_F(t) + a_N P_N(t) + a_S P_S(t) + a_T P_T(t), \quad (1)$$

with the value of the quiet Sun, S_Q, and $a_{F,N,S,T}$ the four coefficients for the influence of faculae, network, sunspots, and the trend from ΔS_T.

Sunspot Darkening

Sunspot darkening, the fractional change in TSI caused by sunspots, is calculated explicitly as

$$P_S = \sum \Delta S / S_Q = \sum \mu A_s \alpha_S \frac{R(\mu)}{\int_0^1 R(\mu)\mu d\mu} \quad (2)$$

where ΔS is the reduction in irradiance relative to the quiet Sun, S_Q, for a sunspot of area A_s (in fractions of the solar hemisphere) at location μ in heliocentric coordinates. $R(\mu)$ is the center-to-limb variation function which is assumed to be the same for the quiet photosphere and the spot and α_s is the bolometric contrast. The summation is over all spots on the solar disk at a specific time, and utilizes bolometric contrast and center-to-limb functions (Eddington limb darkening $R(\mu) = (3\mu + 2)/5$) or more elaborate functions of μ as, e.g., from Pierce [47] appropriate for modelling total or also spectral solar irradiance variations. Ground-based white light images made from 1882 to 1976 by the Greenwich Observatory, and most recently by the U.S. Air Force at the operational Solar Observation Optical Network (SOON) sites. Observations of the sunspot regions are available from the National Geophysical Data Center (NGDC) operated by the National Oceanographic and Atmospheric Administration (NOAA) at Boulder, Colorado, from ftp://ftp.ngdc.noaa.gov/STP/SOLAR_DATA/SUNSPOT_REGIONS,

and supply the basic time-dependent information about sunspot areas and locations. Greenwich sunspot areas are reported to be 20–40% larger than SOON sunspot areas [48, 49]. The differences between these two data sets were determined by Balmaceda et al. [49] and have been confirmed for the period after January 1977 when the USAF/NOAA data started [50]. Hence, they are corrected to agree with the Greenwich data, mainly to get a consistent record for the period from 1882 until present.

Sunspots comprise a very dark central umbra and a less dark surrounding penumbra (see also Fig. 7b), but present versions of P_S do not include this distinction because the SOON data lack the information about the relative areas of umbra and penumbra. The bolometric contrast α is obviously different for the two parts and they depend on the temperature of the umbra T_u, penumbra T_p, the quiet Sun T_0, and the respective areas A_u and $A_s = A_u + A_p$. The combined contrast of a spot α_s is

$$\alpha_s = \frac{A_u}{A_s}\left(1 - \left(\frac{T_u}{T_0}\right)^4\right) + \frac{A_p}{A_s}\left(1 - \left(\frac{T_p}{T_0}\right)^4\right). \quad (3)$$

Equation 3 yields with T_u = 4,240 K, T_p = 5,680 K T_0 = 6,050 K and A_u/A_p = 0.22 a value of 0.32 which was first proposed by Hudson et al. [51]. Figure 8 shows the time-latitude appearance of sunspots, the typical butterfly diagram. From detailed observations of sunspots with the Vacuum Tower Telescope (VTT) of the Kiepenheuer Institute in Tenerife, Steinegger et al. [52] and later Steinegger et al. [53] deduced a size-dependent α according to

$$\alpha_s = (0.223 \pm 0.010) + (0.024 \pm 0.005)\log A_s \quad (4)$$

$$\alpha_s = (0.125 \pm 0.019) + (0.048 \pm 0.010)\log A_s. \quad (5)$$

Equation 4 was generally adopted (see, e.g., [30, 49, 54, 55]). A comparison of the relation of Eq. 5 with results from sunspot data observed by MDI/SOHO [56] shows that this relation is indeed more appropriate [50]. The calculation of P_S presented here is based on Eq. 5 with the average coefficients between their original coefficients and those determined from Mathew et al. [56], α_s = (0.127 ± 0.011) + (0.050 ± 0.006) log A_s. The sunspot data from January 1975 to February 2010 are used to determine P_S and are shown in Fig. 9a (on the plots, P_S is identified as PSI, and they are given in parts per million, ppm).

Solar Constant and Total Solar Irradiance Variations. Figure 8
Daily values of PSI as function of the latitude providing the famous butterfly diagram of sunspots. At the beginning of a cycle, they start at latitudes around ±40° and then migrate down toward the equator. The vertical lines indicate the time of the minima and it becomes also clear that they are determined by the first important sunspots emerging at high latitudes

Brightening by Faculae and Network

Images like Fig. 7a can provide areas covered by plages and bright network in the upper solar atmosphere which in turn can be used to determine the effect of photospheric faculae and network on TSI. Such images are called spectroheliograms because they are observed in a narrow wavelength band in the resonance line of CaII K at 393.37 nm, which is the strongest solar spectral line observable from the ground. Archives of daily spectroheliograms maintained at Kodaikanal Observatory (KKO), India, since 1907, and at Mt. Willson Observatory (MWO), USA, since 1915, provide the longest available record of the daily changing structure of magnetic plages and network (see, e.g., [39], and references therein). Spectroheliograms compiled since 1965 (as Fig. 7a) at the National Solar Observatory (NSO) provide supplementary information. The MWO record was discontinued in 1985 and the ones of KKO and NSO in 1999. These spectroheliograms can be analyzed individually to determine the area and position of the faculae and bright points [39, 57, 58], as it is done from images in magnetograms for the SATIRE model (e.g., [59, 60]).

At Kitt-Peak Observatory, monthly observations of disk-integrated CaII K line fluxes started in 1975 and proved to be a good surrogate for the plage and

Solar Constant and Total Solar Irradiance Variations. Figure 9

Daily PSI (**a**), MgII index as observed (**b**) and decomposed in a long- (MgII-lt: **c**) and short-term (MgII-st: **d**) part. Times of the minima are given as *vertical green lines* and are labelled with the percentage deviation of that minimum from the value of the minimum around 1986 relative to the mean amplitude of the parameter. The *dotted lines* correspond to the parameter if a linear trend between minima is removed

network area covering the Sun. With the start of NIMBUS7, observations of the core-to-wing ratio of the MgII H & K lines, called MgII index [61], became available. Now there is a continuous daily record since November 1978, which is updated weekly with SOLSTICE/SORCE data [62]. The time series of the MgII index used here is shown in Fig. 9b and is separated into a short- and long-term part, MgII-st and MgII-lt. This separation is performed by calculating a running average of the standard deviation over 217 days (eight solar rotations) which is then used – multiplied by an appropriate factor – to define the lower limit of the short-term variations of the MgII index. The values above this limit are the short-term part of Fig. 9d and the values below the long-term part of Fig. 9c. The reason for calling the short-term part the facular contribution is quite clear – it is related to the passage of active regions on rotational timescale. As shown below, the long-term part gets a much higher coefficient from the multi-linear regression analysis. This can be interpreted as coming from small magnetic features, called here the network, which have a higher specific contrast for TSI than larger ones [63]. So the daily MgII-lt values are used for $P_N(t)$ and those of MgII-st $P_F(t)$ in Eq. 1, providing the second and third components of the proxy model. Figure 9c and d illustrate the influence of faculae and network during the recent minimum and show that its value is determined by the small number of faculae and not by the network. This is in further support of the fact that the chromospheric indices do not show a secular trend and confirming the conclusions of a recent study of the long-term behavior of solar-like stars by Judge and Saar [64].

Calibration of the Four Components by Multi-Linear Regression

The value of the quiet Sun, S_Q, and coefficients $a_{F,N,S,T}$ are determined by a multi-linear regression according to Eq. 1 with the extended PMOD composite for $S(t)$. The results are shown in Table 2(a) and Fig. 10.

Earlier results of the two- and three-component models (e.g., [30]) showed that 77.2% and 78.6% of the variance are explained. The four-component model shown here explains 84.4%, which is an important improvement over the three-component model. The use of Eq. 5 instead of Eq. 4 (still used in most calculations of PSI) does not improve the correlation (from 84.3% to 84.4%), but changes the coefficients as shown in Table 2(b) significantly (up to 10-σ of the uncertainty). It is interesting that the PSI uncertainty decreases, whereas those for Mgll-st, Mgll-lt, and the trend increase, the latter substantially. This may indicate that Eq. 5 represents better the change of the contrast during cycle 23 as observed by Livingston and Penn [65]. This is, however, probably more due to a change in size as suggested by Mathew et al. [56] than a real change of contrast.

The trend is well represented by the model with a slope of the TSI–B_R relation of 0.3466 ± 0.0032 which is close to the result of direct correlation with 0.3357 ± 0.1426 (including the minimum value at 1977). That is, within the correlation uncertainty and within 3-σ of the model coefficient uncertainty, they agree. This confirms the need for the fourth component which is related to the strength of the activity, and not to the manifestations of the surface magnetism.

Solar Constant and Total Solar Irradiance Variations. Table 2 Coefficients of the four-component model. Note that the coefficient for the trend agrees within the uncertainty with the result found from the direct regression of the TSI and B_R values at the minima as shown in Fig. 6c

S_Q	a_F	a_N	a_S	a_T	r^2
(a): α according to Eq. 5					
1,364.66	76.17	122.91	−0.7997	0.3466	0.8444
Standard error	1.02	0.73	0.0048	0.0032	
(b): α according to Eq. 4					
1,364.66	78.85	125.39	−0.7515	0.3470	0.8429
Standard error	1.03	0.74	0.0046	0.0033	

Solar Constant and Total Solar Irradiance Variations. Figure 10
Panel (**a**) shows the calibrated long-term MgII-lt (*red*) together with the corresponding trend (*blue*) of the "quiet Sun," and panel (**b**) the calibrated short-term MgII-st (*red*) and PSI (*blue*). Note that all three panels have the same scale. The green curve of (b) shows the 191-day filtered difference between facular and sunspot influence. The net effect of active regions increases TSI during minima by ≈0.08 W m^{-2}, whereas during maxima, TSI is dominated by sunspots and a decrease by ≈0.25 W m^{-2} is observed

This is obviously in contradiction to the vastly accepted assumption that *all* the changes of TSI and SSI are due to surface magnetism. This means that the UV radiation has probably no long-term trend even back to the Maunder Minimum, only changes of the cycle amplitude. On the other hand, TSI shows a long-term trend which could be due to a change of the temperature of the photosphere, which changes TSI but the UV radiation only by a very small amount [38, 45]. As the strength of activity may also be represented by the total number of sunspots during a cycle, this can also be used to determine the long-term trend of TSI (see, e.g., [66, 67]). So, a long-term trend for TSI on top of the amplitude changes of the individual cycles is highly probable. But the same long-term trend cannot be applied to the UV irradiance, which then shows only the important variation of the cycle amplitude.

Future Directions

Observations of TSI during the last three solar cycles have revealed very interesting and partly unexpected variations which challenges the solar physics community. The differences between the behavior of TSI during each cycle are an important test bed for proposed explanations, and at present, the variability can be explained to a high degree (nearly 85% of the variance during the last three cycles), although the understanding of the underlying mechanisms is still incomplete. The success of the four-component proxy model proposed by

Fröhlich [50] and the results presented here suggest two different mechanisms producing irradiance variability, which are both related to the strength of solar activity: (1) related to the manifestations of the surface magnetism during a cycle and (2) related to a global temperature change on longer timescales. This contradicts the assumption that *all* irradiance changes (total and spectral) are due to surface magnetism on solar cycle and secular timescales (e.g., [68–70]), which provokes interesting discussions about the physical mechanisms on the Sun. This controversy has fundamental consequences on the long-term behavior of the UV radiation and needs certainly more analysis. Data from the ascending phase of the just-started solar cycle 24 will certainly deepen the understanding and provide new insights.

Although the understanding of TSI has well advanced during the last decades, there is a need to continue the observations with overlapping missions. This is not only to continue the present TSI record, but also to learn more about the reliability of the understanding, which is "only" based on three solar cycles. As for cycle 23, the next one may be different again and the understanding may have to be revised – a great opportunity for the advancement of understanding the solar engine.

Electric storage cookers Solar cooker with the short-term storage of electricity for cooking during cloudy period.

Global warming Heating of the planet due to the use of fossil fuels and other unplanned human and agricultural activities.

Heat storage cookers Solar cooker with the short-term storage of heat for cooking during cloudy period.

Hybrid solar cookers To cook, bake, and fry meals using clean and free solar energy plus conventional-fuel-like electricity or gas during night and cloudy period.

Indoor solar cooking Cooking inside the house using solar energy.

Multipurpose cookers Modified solar cooker to cook, bake, and fry meals and heat water, purify water, and dry agricultural products.

Multivoltage solar-electric cooker Solar cum electric cooker with 12-VDC electricity (direct current) and 110-VAC electricity (alternating current) cooker.

Solar cookers To cook, bake, and fry meals using free and clean solar energy.

Solar dryer Dehydrate agricultural and marine products using solar energy for long-term storage.

Definition of the Subject

Based on the 31 years of experience, the author in this entry will like to inform the use of different types of cookers and some driers to cook, bake, and fry meals and dehydrate agricultural products using solar energy. These simple and practical devices and use of clean fuel will not only save conventional fuels but will also help in the reduction of pollutants and thus global warming.

Introduction

Food processing is the integration of various processes to get the required product of given quality at the right time, using the minimum fuels and minimizing the adverse impact on the environment. Conventional fuels like oil, coal, and biomass are used to achieve this, spending expensive budget and creating deforestation, air pollution, and global warming.

There is no simple solution to revert this global warming; however, as mentioned by Al Gore 2007, shared Nobel Prize Winner for peace, some possible steps are conservation of energy, recycling of materials, use of renewable sources of energy, etc. The use of solar energy – clean, abundant, and free fuel – to reduce the consumption of firewood or fossil fuels is one of the possible solutions.

During last 30 years, the author has studied many solar thermal devices for different processes like heating water, drying, and cooking meal at domestic level. The details of these devices are published in technical journals and conference proceedings [1, 2]. Depending on the need, one or more of these devices can be used. We will be mentioning only cookers and dryers, mainly for domestic uses.

Solar Driers

All the agricultural and marine products contain a lot of water (60–90%) which cannot be stored at the ambient temperature for a longer period, even for a week, because of the microorganism and internal humidity. The purpose of drying is to separate the water contained in solids. When products are dried (dehydrated) to 14–20%, it significantly decreases respiratory activity and controls associated microorganisms, which allows storage of the products in the closed environment for a period of 6–12 months, without losing its nutritional and organoleptic properties.

Drying is one of the oldest applications of solar energy for preserving the food and meat. Egyptians were using direct sun radiation for drying fish 4,000 years ago.

Basically, there are two types of driers [3, 4].

Direct Solar Dryer

It consists of a metal box whose bottom is insulated and has a sloping single glass cover, which is arranged on the box to receive/transmit solar radiation (Fig. 1). At the bottom of this box, a metal sheet painted black is kept. The materials to be dried are placed in a metal tray with mesh placed over the plate. The front or bottom of the dryer has various holes for the entrance

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 1
Concept of passive solar dryer: *1* Sun, *2* outer box, *3* transparent glass, *4* entrance of ambient air, *5* tray with products, and *6* exit of humid air

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 2
Direct solar dryer made for the community to dry cashew nuts fruit

of ambient and humid air. The back of this dryer has also various holes (at a level higher than entrance) for the exit of humid air coming from the products to be dried.

The direct dryer, although simple to make, has some inconvenience, like exposure from direct sunlight which can be harmful to food in terms of quality (natural color loss, destruction of vitamins, and nutritional value). Therefore, it is not recommended for drying light-sensitive products like coriander and other herbs.

Many driers have been made [3, 4], but to explain the concept, Fig. 2 shows one constructed (4 m^2) for local community (Puriscal) to dry cashew nut fruit. This cashew nut has many uses: fruit, nuts, as well as to make alcohol.

In 1998, a model similar to this was designed and constructed for a rural community (Costa Pajaros, Puntarenas). Since then, it is being used for drying and selling herbs (medicinal plants) for tourists and thus serves as an income generation.

Indirect Solar Drier

In order to minimize the effect of direct sun rays on the products, one can use the indirect solar drier. It has basically two components, air heater (similar to water collector) to heat air to reduce its water content and a drying chamber where the products to be dried are kept in different trays.

The ambient humid air enters the air collector; it is heated, and hot dry air leaves the collector and enters in a chamber. Inside the chamber, there are various trays separated from each other to place the product to dry, especially those sensitive to direct sunlight. In this case, warm air from the air heater passes through the trays and removes the moisture from the product, which goes through a hole at the top of the chamber. In order to increase the flow of air and, hence, performance of the dryer, one can use either chimney or a small fan [4].

Figure 3a shows the concept of indirect solar dryer, and Fig. 3b shows a solar drying plant of 600 m^2 for coffee designed and partially financed by Canadian Ministry of Energy and installed at Coopeldos, Guanacaste, Costa Rica. This is a hybrid plant and uses biomass (coffee waste) as backup.

Combined Solar Dryer

In this case, dryer includes both concepts for drying. This dryer can be used for standard products and other highly sensitive with regard to light. Figures 4a and b show one dryer designed and studied by author in 2007 [4, 5].

Here, the circulation of air through the products is via natural circulation using chimney, whose height could be varied (0.8–1.4 m). Increase in air temperature of 40–60°C was observed in the solar dryer. Also, the initial humidity of ambient air (60–80%) was

reduced to 11–14% at the exit of air collector and to 10% inside the solar dryer. In the more recent model [4], a small fan run with solar panel and automatic control was added.

Now, we pass on to the cooking.

Cooking of Food

Eating is one of the habits/processess which is very much required as it provides fuel to run one's body – rich or poor. Food supplies the body with nutrients for growth and energy. Thus, we are what we eat. Therefore, if we improve the quality of cooking capability, we improve the quality of life.

Somebody once correctly said:

- We can't sleep well,
  We can't think well,
  We can't love well, if
  We don't dine well.

I would add to this: "We can't dine well if it is not cooked well." In order to have food cooked well, we need to have good cookers: it has to be the solar cooker – an excellent device based on personal experience of research, dissemination, and use in the family.

Energy and Temperature Required for Cooking

Cooking needs good quantity of energy especially in developing countries – may be from 10% (urban area) to 80% (rural area) of the domestic energy need.

Half of the world's population cooks their food over firewood. According to the United Nations, one in every four people on earth suffers from fuel wood shortages. Increased use of firewood causes the spread of deforestation, resulting in soil erosion, flooding, famine and loss of wildlife, more CO_2 emissions, and finally climate change. Table 1 shows the various temperatures required for different processes related to cooking.

It can be seen that the temperature required for cooking is not high, about 80–100°C. Thus, solar energy – free, clean, and abundant fuel – can be used for this purpose. Higher temperatures than this only reduce the cooking time and also quality of food.

History of Solar Cooking

In general, concentrators and hot boxes are used for cooking and other applications. The concept of the solar concentrator is about 4,000 years old when the Greek philosopher Archimedes used some reflecting material to burn the Roman fleet in 2300 BC. The concept later on was used for other purposes and also for cooking. On the other hand, concept of the hot box is over 230 years. In 1776, Benedict de Saussure, a Swiss alpinist using a simple box with various glasses on the top and solar energy, could attain temperature of around 90–100°C. There are some indications of baking of fruits by him. In 1780, Ducarla, a French scientist using hot box and five glasses could cook meat in 1 h (Fig. 5).

In the year around 1889, US patent was issued to W. Calver on solar stove. Both types of cookers, concentrating and hot box, have been studied for the last 100 years, and many governments have been encouraging their promotion since oil crisis in 1973.

Different Types of Cookers

Although there are over 100 models around the world – made, distributed, taught, and even sold commercially – they all can be divided into three main categories: the hot box type, the concentrating type, and vapor type [6].

Hot-Box-Type Cookers

As the name implies and shown in Fig. 6, it is made of a wooden/metallic box, with galvanized iron metal sheet painted black on top to absorb maximum solar radiation, glass wool as heat insulation, and single or double window glass to allow low-wavelength solar radiation and, at the same time, impede the exit of higher-wavelength radiations emitted from hot plate.

Solar Cookers and Dryers to Conserve Human and Planet Health. Table 1 Temperatures required for various cooking processes

Process	Temperature required, °C (°F)
Room temperature	22 (72)
Most germs cannot grow	49 (120)
Water pasteurization	65 (150)
Food pasteurization	71 (160)
Food cooks	82 (180)
Water boils (at sea level)	100 (212)

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 5
Concept of hot box to cook and bake food in 1776–1780

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 6
Hot-box-type cooker: *1* two transparent window glasses, *2* metallic plate, *3* heat-insulating material, *4* reflecting sheet, *5* door to keep and take out cooking pots, *6* rod with some holes to adjust reflector angle, and *8* outer box

The air in the box is thus heated through the greenhouse effect and is used for cooking meals. The box can have one or more reflectors to increase the amount of solar radiation. This model can be used for cooking and baking.

Concentrating-Type Cookers

This is another type of cooker also used worldwide, mainly for frying meals. As shown in Fig. 7, here, solar radiation is received by a shining parabolic surface and is reflected at the focal point where the food to be cooked is kept. The simple equation to make proper parabola so that the direct solar radiation is reflected to focal point (or cooking pot) is:

$$Y = X^2/4F,$$

where F is the focal length required. X and Y are the coordinates in axis X and Y, respectively.

Depending on the requirements, ease for users, the focal point could be either inside or outside the parabola. In addition, the parabola can be fixed and the focal point movable, or the focal point can be kept fixed while the parabola is movable. These models although produce higher temperatures as compared to box types; however,

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 7
Concentrating-type cooker

for its working, one needs clear sky as well some manual or continuous tracking of concentrator.

Vapor-Type Cookers

This type is designed to cook inside a house. As shown in the Fig. 8, here, a flat plate water collector (or concentrator) is used with either water or oil heated in tubes. This hot fluid rises through a thermal syphon to another insulated box (with cooking pot) kept inside the house. After the hot liquid or vapor transfers heat to the food kept in the box, it is condensed and returned to the collector for further heating.

Figure 9 shows a design by Augustin Mouchot of France in 1870, which uses all three concepts to cook, bake, grill, and fry food by just changing the position.

In order to enable these solar cookers to be used during cloudy periods or at night, two additional types of cooker have been developed.

Hybrid Cookers

In hybrid cookers, solar energy is integrated with conventional energy sources, such as electricity, gas, or

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 8
Solar cooker based on vapor for cooking inside: *1* Sun, *2* water heater, *3* metallic plate, *4* metallic tubes, *5* transparent glass, *6* inlet of water, *7* exit of vapor, *8* cooking chamber, and *9* cooking pots

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 9
La Marmite Solaire by French Augustin Mouchot in 1870 for cooking, baking, and frying meals

firewood. The switching between two fuels could be manual or automatic. One example of this type of cooker is an electric/solar oven, which was designed by the author in 1986 and will be explained later on [7].

Energy Storage Cookers

Storage cookers store solar energy in the form of:

- Heat (sensible or latent) – Using different solids, liquids, or salts [8, 9].
- Electricity – Here, the DC electricity generated from solar cells is stored in a battery, which can be used for cooking directly [10] or can be converted in AC to be used with a conventional AC device including microwave oven [11].
- Hydrogen – The electricity from the solar panel is used to electrolyze water to produce oxygen and hydrogen. Hydrogen is stored in a tank and can be used for cooking at any time. This system, designed by Fraunhofer Solar Energy Institute was installed in 1994 at the self-sufficient solar house at Freiburg, Germany [12].

Author's Work: Personal Interest in Solar Cooking

For the last 32 years, the author has designed, constructed, studied, published, promoted in many countries and even used at home various types of cookers – hot box types, hybrid solar-electric (110 VAC and 12 VDC), solar-electric microwave oven, cooker with dryer, with water heater/pasteurizer, etc.

Although the details of various cookers can be seen in various articles, we can mention in brief some of our cookers with corresponding references.

Food Warmer

The main source of electricity in this country was, and still is, hydropower. Like most people, I was using an electric range for cooking at my house. At the start of 1979, due to high solar radiation, there was a shortage of water in rivers; this resulted in a shortage of electricity generation. Due to this, national electricity utility, Instituto Costarricense de Electricidad (ICE), decided to ration electricity for 2 days a week, from 7 am to 5 pm. Thus, we made a simple solar hot box at house to warm food cooked the previous night. As shown in Fig. 10, basically, it is an insulated wooden box and a galvanized iron metal sheet painted black, glass wool as heat insulation and one window glass on top to reduce the heat losses (Fig. 10). The solar radiation (low wavelength) passes through transparent glass and is absorbed by black paint. With this, the metallic plate is heated. Now, the metallic hot plate also emits the radiation but in higher-wavelength region (heat). To reduce the heat losses at four sides and at bottom of the box, heat-insulating material like glass wool is used. The same window glass on the top of the box impedes the transmission of heat radiation, with the result: the air in the box is heated and can be used for warming food.

The maximum air temperature in solar oven reached up to 80–90°C, and three to four meals could be heated during midday in 40–60 min [13]. Material's cost was approximately US$ 10–15.

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 10
Simple low-cost solar food warmer (March, 1979)

Simple Hot Box Oven

After observing the success with food warmer, it was decided to improve the box and convert into a solar food cooker. Two changes were made in the solar food warmer mentioned already. Firstly, we added another window glass on the top of the box to reduce heat losses, and secondly, we used a reflector to increase the solar radiation during the day. Reflector can be adjusted (recommended) every hour or two. Figures 11a and b show the improved solar oven constructed in 1982 and still in use [14] at author's house.

This reflector also acts as an insulator to keep the food hot. With these two changes, the maximum plate temperature was increased to 150°C with no food inside and 110–130°C during cooking.

This has been used for cooking, baking, roasting food (rice, beans, vegetables, lentils, meat, deserts, etc.), and also for purifying tap/river water from microbiological point of view (pasteurization). This model cannot be used for frying meals which requires the temperature of oil as 180–200°C. On an average sunny day, three to four meals can be cooked in 2–4 h. Once convinced with its working, another cooker was made with stainless steel as an outer box for family use (Fig. 11b). Figure 12 shows some of the meals cooked [15].

In 1984, we got the national patent on this solar cooker/oven. (*No. 2367*). This type is the most common type of solar cooker used worldwide.

Concentrating Cooker

Figure 13 shows one of our parabolic cooker assembled based on model developed by a nonprofit organization, EG Solar in Germany [16]. This model produces higher temperature (about 350–400°C); however, for its proper working, it needs the direct radiation, perfect shape, and some frequent (15–45 min) tracking.

Some Problems Although it is expected that one will keep the items to be cooked in solar cooker when it is sunny, however, there are few days when sky looked clear in the morning when you put the food, but the

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 11
(**a**) and (**b**) Solar ovens constructed in 1980

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 12
Some meals cooked and baked with solar cooker/oven

climate changes after 1 h or 2, especially in central American region, due to sea on both East and West coasts. Depending on the quantity of food and the climate, the food may or may not be cooked properly. Although this could happen only 15–30 days a year, some aggressive promoters will say no problem and will suggest the user to take the partially cooked food on conventional stove and finish the cooking. However, within few days of using solar cooker, practically, no housewife will love this idea, and this could be sufficient reason to get frustrated. Fortunately, this happened with my wife, and it compelled me to look for a solution. Thus, hybrid cooker was made in 1986.

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 13
Solar concentrating cooker in use

Hybrid Cookers (Sun – AC Electricity)

In hybrid cookers, solar energy is integrated with conventional energy sources, such as electricity, firewood, or other fossil fuels (as backup fuel).

Designed in 1986 and as shown in Figs. 14a and b, it is similar to a hot box oven, but the black metallic plate has an electrical resistance beneath and a thermostat to regulate the temperature [7]. The hybrid cooker is connected with electricity, and the thermostat is fixed at 90–100°C. If solar radiation alone enables the system to reach this temperature, electricity will not be consumed. If the solar intensity falls below this, and plate temperature does not attain the required temperature, electricity is connected automatically to the electric plate to raise the temperature and is disconnected if the solar intensity is increased.

With these types of devices, your meal is cooked at the right time with the reduced consumption of conventional fuel, as electricity in this case.

To see really the effectiveness of the device, consumption of electric energy during cooking could be measured with the simple electronic timer or watt-hour meter.

Although it looks strange to convert electricity (high-quality energy) into heat (low-quality energy) and use it for cooking, it is worth mentioning that it could be justified, to some extent, in countries where good percentage of electricity is generated from renewable sources. In Costa Rica, 85–90% of electricity is generated from water, wind, and geothermal.

Hybrid Cooker (Sun – Gas)

This model was made in Honduras as a collaboration project. As shown in Figs. 15a and b, in this case, beneath the metallic plate, various tubes are soldered for passing the LPG gas. Rest is the same as the conventional model. Here, both fuels – solar (first choice) and gas (backup) – are used [17]. It is worth mentioning that model works fine with minimum quantity of gas.

Electric Storage Models

In the hybrid model mentioned already, the electricity from the conventional source (110 VAC) was used; thus, it could be used only at places connected to the electric grid. There are many families/places (like farm house, ecological cabins) which are not connected to electric grid. Thus, we designed other models using electricity generated from photovoltaic panels and solar energy. Comparatively, high cost of the new cooker is not first concern for some environment-conscious people.

Here, photovoltaic panels are used to convert solar energy in DC electricity. This is then stored in deep-cycle batteries. The stored electricity in 12-V battery is used directly for cooking or converted in 110 (or 220) VAC through an inverter, which can be used efficiently for running conventional 110-VAC microwave oven. This could make sense for the remote places for rich and/or nature-conserving persons.

Solar-Electric Microwave Oven Figures 16a and b show the setup for a microwave oven (700–800 W) using solar panel, battery (12 V, 100 Ah), and an invertor (1,500 W). Cooking with microwave oven [11] is fast and efficient. It heats the food internally and to temperatures higher (in general) than conventional solar ovens.

For a mostly clear day with insulation of 5.0 kWh/m^2/day, about 300 Wh of energy is collected and as the overall efficiency of the battery and inverter used is about 65%; thus, 200 Wh is available for microwave cooking. This is sufficient for 20 min of cooking with the 700 W microwave oven. If more microwave cooking time is routinely required, another PV panel and battery could be added to increase collected and stored energy each day.

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 14

(**b**) Hybrid solar oven combined with 110-VAC electricity (1986)

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 15
(**a**) and (**b**) Hybrid solar oven with LPG as an additional fuel in Honduras (2000)

Real cooking has been done; however, this is used mostly in our solar house daily by four to six colleagues for warming their lunch.

Portable 12-VDC Cooker In this case, no inverter (device to convert DC electricity into AC electricity) is used. One commercial 12-VDC portable cooker, which runs mainly with car cigarette lighter, was bought in USA and converted so that it could be used with electricity produced from solar energy. Although 12-V battery was used, no inverter was required. Figures 17a and b show the model. The power of the cooker was found in the range of 100–190 W [18]. The real cooking has been done.

Solar Multivoltage Cooker Based on the previous experience, another model was designed, constructed, and studied. The basic model is the same as conventional hybrid (sun electric) model (Fig. 14b). Here, the electric plate was not bought, but rather designed and constructed by us. Here, we have used eight electric resistances in the form of rods and riveted them firmly

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 16
(**a**) and (**b**) Solar-electric microwave oven at our solar house (1994)

underneath a metallic aluminum plate. To operate them with 12 VDC, we connected these resistances in parallel (maximum power, 190 W), and for 110 VAC, we connected them in series (maximum power = 336 W). Finally, we have two sockets outside the box.

There is a thermostat which is used for the regulation of temperature. Figure 18 shows the final model. In other words, depending on the connections, the cooker could be used with 12 VDC or 110 VAC [10].

Again, this is studied directly with solar energy and/or with stored electricity. Some of the important results are, with charged battery (90 Ah), 500–600 g of food could be cooked in 2–2.5 h. The time is reduced when additional solar energy is used. Also, this battery could be charged in 1 day with one 100-Wp panel.

This hybrid solar-electric, dual-voltage (12 VDC/110 VAC) oven can be used in electrified as well in nonelectrified regions.

Multipurpose Device

Cooking needs higher temperature thus requires high solar radiation. Thus, depending on the climate/solar radiation at a given place, solar cooker can be used for

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 18
Multivoltage sun electric oven (2008)

6–9 months in a year. On the other hand, water heating (and drying) needs less temperature and thus low solar radiation. It means that if the same cooker (with some modification) can be used for both purposes – cooking and water heating (or drying) – it can be used for more period (8–10 months). With this objective, multipurpose device was designed, made, and studied.

Solar Cooker cum Water Heater

As shown in Fig. 19a, this is similar to conventional hot box solar oven except that the flat absorbing plate is replaced by an aluminum U-shaped tank. The dimensions of this tank are such that total capacity is 50 l maximum. The tank has an inlet for cold water (at the bottom) and an outlet for taking hot water at the top of the tank.

The top surface of this tank (0.5 m^2), exposed to solar radiations, is painted black to absorb the maximum sun rays. This complete tank with a flat base like a valley with a capacity of four to five cooking pots is enclosed in another metal box with glass wool as a heat insulation on four sides and at the bottom (Fig. 19b). On top of this box, there are two normal window glasses as covers and one reflector. The reflector can be adjusted at different angles through a metallic bar with different holes [19].

For cooking purpose, no water is filled in the tank and the pots with food are kept in the valley space. The maximum plate temperature could reach up to 137°C (without any load) and 108–100°C (when 2–3 kg of food was used for cooking purpose).

To heat water, 30–50 l of water can be filled in the tank. Forty liters of water in the tank could be heated to 40–42°C. In another experiment after cooking 2 kg of

(**a**) and (**b**) Solar cooker cum water heater at our solar park (1993):*1* base for solar device, *2* metallic plate, *3* outer case, *4* inlet for cold water, *5* glass tube to see water level, *6* water for final use, *7* metallic plate, *8* reflecting sheet, *9* transparent glasses, *10* rod with various holes, and *11* wheels to rotate the device

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 20
(**a**) and (**b**) Solar cooker cum dryer in our solar park (1993)

food, 10 l of water was added in the tank at 13 h and 30 min, it could be heated to 39°C.

The objective of the present system is not to heat the large quantity of water for bathing but to heat little quantity of water for dish washing, making coffee, and other uses, either after the cooking is finished (sunny days) or instead of cooking, during cloudy period. [19].

Solar Cooker cum Dryer

As shown in Figs. 20a and b, it has a conventional hot box oven with galvanized iron plate painted black, as an absorbing surface and two normal inclined window glasses (separated by a distance of 2 cm) as covers and one reflector. In addition, it has various holes in front of the oven for entrance of ambient air and holes at the back of the oven for the exit of hot humid air. To introduce the food to be cooked or products to be dried, there is a door at the back of the device. The whole box has glass wool insulation on the four sides and under the metallic plate.

Again, the objective is not to use the device for the both purposes at the same time [19, 20].

The maximum plate temperature without load (food or drying products) reached to 140°C.

For cooking purpose, all the holes are closed and the food is kept in normal metallic utensils. In addition to cook normal meals, it has been used for drying onion, meat, turmeric, and cauliflower.

To use as drier, instead of cooking utensils, some perforated trays with products to be dried are kept on the top of the absorbing sheet. To control quantity of air flow, any number of holes could be closed on both sides and the rest remained opened. In one particular case of cauliflower (April 1993), during 3 days of experiments (partially sunny climate) 2,329 g of cauliflower (bought at cheaper rate), cut into small pieces, could be dried to 247 g. Thus, the quantity of water evaporated was around 89%. This could be stored in plastic bag. When cooking of this was required, cauliflower was rehydrated (by soaking in water) for 15–30 min, removed water, and then it was used for cooking.

Multipurpose and Hybrid Food Processor (Solar-Electric 110-VAC Cooker/Water, Pasteurizer/Still, and Dryer)

Many devices mentioned already were combined to design and construct a single device – hybrid food processor – to cook, pasteurize water, dry different products, demineralize water, etc. As can be seen in Figs. 21a and b, the model is conceptually similar to a conventional solar oven and is made of inclined stainless steel box with an outer dimension of 0.54 × 0.35 m and 0.20-m high in front and 0.25-m high at the back side. It has an electric black plate as an absorbing surface with an area of 0.13 m^2 (0.45 × 0.28 m) and two normal window glasses on the top separated by a distance of 2 cm. It also has one reflector made of bright stainless sheet. Again, an electric plate has a resistance as well a thermostat to regulate the plate temperature. To introduce the food to be cooked or products to be dried, frame with two glasses can be lifted. To use as a dryer, the box also has two holes in front of the oven for the entrance of ambient air as well as another three holes at the back of the oven for the exit of hot humid air. The metallic tray(s) with the products to be dried are kept at the top of the absorbing plate. The holes could be closed for cooking and pasteurizing or opened for drying.

Again, as many processes (like drying, distillation, etc.) need less temperature and thus less solar intensity, as compared to cooking, the device can be used for more number of days.

On a sunny day and without any load, the plate temperature, only with solar radiation, can reach to about 130–150°C. It works fine. During the partial cloudy days, absorbing plate is connected with electrical energy, in addition to solar, to realize the process required [21].

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 21
(**a**) and (**b**) Hybrid fuel food processor (2005): *1* electric plate, *2* electric power and thermostat, *3* reflector, *3A* rod to adjust reflector, *4* holes for air entrance, *5* holes for the exit of humid air, *6* outer box, *7* electric timer, *8* bottle for final distilled water, and *13* trough/gutter for distilled water

Food is cooked with only solar and/or combined with electric energy, consuming the minimum quantity of electric energy if required. Cooking time is between 2 and 4 h depending on the climate and the quantity of food. Real cooking is done many times (Fig. 22a).

On one particular day to cook 2,156 g of meal (additional weight of pots, 835 g), 410 Wh of solar and 400 Wh of electric energy (worth US$ 0.025) was used. Total input energy is 810 Wh or 696.6 kCal.

Effective Efficiency,

$$\eta = \frac{\text{Useful energy gained by food (vegetables and cake)}}{\text{Total input (solar + electrical) energy}} = \frac{M_F * C_F * \Delta T}{A_P \int Hi\ dt_S + P_E * \int dt_E} = 158.8\text{kCal}/696.6\text{kCal} = 22.8\%.$$

Where

M_F mass of food (kg)
C_F specific heat of food (kcal/kg°C)
ΔT rise in temperature (°C)
A_P area of the absorbing plate (m^2)
P_E power of the electric plate (W)
H_I solar intensity on horizontal surface (W/m^2)
dt_S and dt_E time of solar and electric consumption.
Here, we have taken specific heat of food as that of water, 1 kCal/kg°C.

It has been known that heat can deactivate pathogenic (disease-causing) microbes. Although it is recommended that contaminated water can be made safe by boiling, it is also true that same water can be pasteurized (drinkable) at temperatures well below boiling, at 67–70°C, depending on the time.

To use the device as a dryer (Fig. 22b), holes in front and at the back are opened during the sunny (drying) period and are closed after sunset or during rainy period. The metallic tray(s) with the products to be dried are kept at the top of the absorbing plate. The real solar drying has been done with various domestic products (like tomatoes, coriander, onions, pineapple, etc.).

To minimize the color loss, in case of green coriander, it was covered with a perforated metallic tray to reduce the direct solar radiation.

Two Compartments Oven

Mainly for research purpose, double-compartment solar oven was designed, constructed, and studied by author and other collaborators [22] at Fraunhofer Solar Energy Institute, Freiburg, Germany, in 1996. As shown in Fig. 23, it is similar to conventional oven explained already, except that it has two identical compartments, so that two different comparative studies can be made under the similar climatic conditions. This box has been used for (a) comparing the performance of a metallic slab filled with a phase change material for short-term heat storage, with a conventional absorbing sheet, (b) the use of selectively coated, as compared to a normal black-painted cooking pots, (c) pasteurization of water in glass jar and metallic pot, and (d) for finding the overall heat coefficient and thermal capacity of the box [22].

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 22
(**a**) and (**b**) Food processor in the mode of cooking and drying mode

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 23
Double-compartment solar oven mainly for research purpose (1996)

Using some phase change materials, 30–40 min of heat storage was possible for cooking during partially cloudy period. Also, in addition to cooking, it was used to pasteurize (65–67°C) 14–16 l of water, inactivating most of the pathogenic germs [22].

Some Models of Other Authors

Not all users have the time, tools, or skills to make even a simple solar cooker, but they require one. They can either buy in the local market or import. Fortunately, there are many commercial models of hot box and concentrating-type cookers, ranging from $15 (Cook Kit for single family) to $10,000 (large hybrid cooker for multimeals), available in many countries [23]. Figure 24 shows an exhibit of solar cookers at Granada, Spain, in 2006.

Using the various concepts described above, solar cookers have been made in both developed and developing countries. We will just describe in brief two models: cheapest and expensive one.

Cook Kit Model

One of the simplest cooker was designed by Solar Cookers International, nonprofit organization, to promote solar cooking worldwide and based at Sacramento, CA, USA [6]. Designed and constructed in 1998, using cardboard and aluminum foil, in such a way that when faced towards sun, the solar radiations are reflected at the focal point where cooking pot (or heating jar) is placed (Fig. 25a). In order to reduce the heat losses, the cooking/heating pot is covered with one plastic bag. The device is light with its own advantages (carrying/transporting) and limitations (gone with the wind). Fifteen to twenty thousand of these Cook Kits have used for cooking and water heating mainly in refugee's camp in Kenya for refugees from Somalia, Sudan, and Ethiopia.

In another model (Hot Pot) designed and promoted by another nonprofit organization, Solar Household Energy (SHE), the cardboard is replaced by thin, shining reflecting sheet (Fig. 25b) and the metallic cooking pot is covered with inverted Pyrex container to reduce the heat losses [24].

Hybrid Concentrating Model

Mr. Wolfgang Scheffler [25], designer from Germany, and Deepak Gadhia [26], developer and manufacturer from India, are promoting solar cookers on large scale for schools, temples, and meditation centers in India

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 24
One of the exhibit of solar cookers at Granada, Spain (2006)

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 25
(**a**) and (**b**) Simple and cheap solar cookers – Cook Kit by Solar Cookers International (1998) and Hot Pot by SHE (2002)

and other countries. It is based on a parabolic concentrator (single or multiple, each 3–10 m^2) which focuses the solar radiation at the focal point for cooking inside the kitchen. In this case, the focal point is fixed, whereas the concentrator is tracked automatically with chain, pulley, motor, timer, etc. Figure 26 shows the cooker at Valsad, Gujarat, in India to cook for 30–50 persons. Similar system is also installed by Dr. Luis Saravia and collaborators in 2005, from University of Salta, in Northern Argentina [27]. It does cooking and baking for 50 students.

Figure 27 shows the world's largest solar steam cooking system with 106 solar concentrators of 9.4 m^2 each installed at Tirumala Tirupati Devasthanams to cook for 15,000 persons (30,000 meals). These concentrators are tracked automatically and heat water in cylindrical pipes (kept at focal line) to produce high-pressure steam which is transported inside the kitchen, and food is cooked in big vessels [26]. Also, the system uses propane gas, whenever required.

Advantages

Solar cookers have many advantages like energy, economy, health, social, and for the planet [15, 23, 28]. We will mention in brief.

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 26
Solar cooker at Valsad, India, for cooking 40–50 meals (1995)

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 27
Big solar cooker using steam at Tirupati Temple, India (2009)

Energy Saving

With an average solar intensity of 3.5 kWh/m^2/day, the maximum plate/air temperature in hot box oven can reach to about 150°C without any food or load inside and between 100°C and 120°C while cooking. In the case of concentrating cookers, the temperature will be in the range of 300–400°C. Normally, three to four meals can be cooked in 3–4 h. As an example, based on these data and knowledge of climatic conditions, a single family in Costa Rica (4–6 kWh/m^2/day) can use solar oven for 7–9 months in a year. This can save 1,000 kWh of electricity, 240 l of propane gas, or 725 kg of firewood per year.

Cash Saving

Depending on the cost of the fuel, including transportation cost, one can calculate the amount of money saving using solar cooker. Payback period could be between 8 (rural area) and 24 (urban area) months.

Human Health

Food being cooked with no or less water and at low temperature (less than 100°C) retains most of the nutrients as proteins and vitamins [29].

Studies have also shown that women who cook over indoor firewood are more likely to have active tuberculosis. Children exposed to indoor smoke are two or three times likely have higher respiratory infection. Indoor air pollution from the burning of solid fuels kills over 1.6 million people, predominately women and children, each year. This is more than three people per minute. Solar cookers (smokeless stove) will definitely help in keeping the health better.

Social Aspects

There are at least 2,500 million persons (500 million families) in developing countries that cook with firewood. Children and women in many developing countries have to walk 4–8 h a day to look for firewood.

Free firewood is no longer available to many families since most of the forests have been destroyed by improper uses, for cattle feeding, timber, cooking, and years of drought. Even where sticks, branches, or bushes can be collected from the fields, the chance of being injured, attacked, or even raped are well reported/documented in the literature.

People, combining solar cooker with conventional fuel stove, will need less conventional fuel (especially firewood) and have not to walk daily, could be once every third or fourth day to look for firewood. Reduced use of firewood for cooking will lead to less deforestation.

Environmental Aspects

One of the main greenhouse gas, CO_2, is emitted if cooking is done using firewood stoves or from electric range when the electricity is generated from thermal (coal or oil) plants.

As most of the rural people use firewood for cooking, we can make some approximate numbers from the saving through the use of solar cookers.

One family solar cooker (0.20–0.25 m^2 of absorbing area), using 7–8 months in a year, can save about 750 kg of firewood per year. Knowing the carbon content of the firewood and through the chemical reaction ($C + O_2 \rightarrow CO_2$), one can find the emission of CO_2 from direct burning. On the other hand, cutting of trees for getting firewood also avoids the absorption of CO_2. Adding these, one can show [28] that one family solar cooker can reduce the emission of about 1.6 t of CO_2 per year. Assuming that only 5% of the families cooking with firewood (500 million) use solar oven, this can prevent roughly the emission of 40 million tons of carbon dioxide per year.

Other Uses of Solar Cooker

Solar cookers, in addition to cook food, can be used for many other purposes [30]. One of the most important of these is the pasteurization of water (Fig. 23b). As shown in Table 1, if water is heated to 67–70°C, almost all of the microbes affecting the quality of the water are eliminated; the water is pasteurized and can be drunk safely. The automatic water pasteurization indicator (WAPI) promoted by Solar Cookers International of the USA is used to conveniently check the portability of water [6, 30].

In recent years, directors of the some schools and colleges are asking for solar cookers for warming lunch of the students during midday. The objective is to reduce the buying of more microwave ovens and consumption of electricity. Figure 28 shows just one of the solar oven (1.5 m^2) designed by us and installed in 2005

Solar Cookers and Dryers to Conserve Human and Planet Health. Figure 28
Use of solar ovens for warming lunch at educational centers, Costa Rica (2005)

at Claretiano College in Heredia, Costa Rica. More have been installed at different places including at our university.

Also, in many communities, it has been used to dry/toast herbs and maize and even melt paraffin to make candles, etc.

Number of Solar Cookers Globally

According to a survey carried out by the author few years ago, about 1.7–2 million solar cookers of all types have been manufactured, sold, and distributed freely or at subsidized price around the world including 1.1 million just in China and India in the last 30 years. The number is very low if we compare with other cooking devices used only by rural people:

- Firewood stoves – over 800 million
- Improved firewood stoves – over 140 million
- Biogas stoves – 3.3 millions only in India

Thus, in spite of the fact that solar energy is a pollution-free fuel, that solar cookers have many other advantages, it is not used on a massive scale. Just another comparison, only in the last 15–20 years, more than 3,000 million mobile phones are used worldwide.

There are many reasons (limitations) for this, including the fact that even now, not many people have heard or seen a working example of a solar cooker, and other reasons are unstable climate, not having proper backyard and balcony, not available on the market, more time to cook, cannot be cooked at night and in cloudy period, no post service, comparatively high initial cost, cultural and social aspects, etc. [31, 32].

What Can Be Done to Extend the Use of Solar Cookers

There is no doubt that solar cooking has many advantages; however, we cannot forget that it has some limitations too. On the other hand, conventional fuels like firewood and gas, although haves limitations as deforestation and global warming, however for the most of the users it is not the primary concern. On the other hand security/avalability of the fuel in any quantity and at any time is most important. Thus, one should not expect massive use of solar cookers. It does not mean that nothing should be done to preserve the planet.

Although there is no magical answer, there are various steps that could be undertaken to increase the awareness and use of solar cookers. Some of these could be [31, 32]:

- Use of different medium of communications to inform, show, and convince people about the use of solar cookers.
- The designs of the solar cookers should be appropriate for the needs of the people and communities for which they are intended.
- The buyers should be taught the proper uses of the solar cookers.
- The users should be informed of both the benefits and limitations of solar cookers – including very clearly that the device is intended to save and not to substitute conventional fuels.

Thus, with the combined efforts of designers, manufacturers, promoters, government, users, etc., its use could be increased.

Conclusions

There are more than 200 varieties of solar cookers for different requirements – cheap (US$ 5–10), expensive (US$ 500–10,000), small (cook for three to four

persons), bigger size to cook for 30,000 persons, etc. However:

1. Weak benefits like deforestation, soil erosion, global warming, and national foreign debt are not the primary worry for most of the users (except talking collectively at the national and international meetings), as compared to their daily problems.
2. For most of the users, the convenience, assurance, and necessity of the fuels even at slightly higher price (paid each month) are much more important than another fuel not completely reliable and inconvenient to use even at lower price.
3. Use of solar cookers cannot be expected on a mass scale neither in rural area due to high initial cost nor in urban due to other priorities and the availability of convenient fuels.
4. However there are many places (a) where the solar radiation is high and constant for more than 6 months, (b) where there is real shortage of fuel, (c) like ecological lodges and (d) still some energy/environment concious people exist etc. Here the solar cookers can play an important role.
5. They (solar cookers) should be available in different varieties, subsidized properly, but, more than that, taught to use properly and informed advantages without exaggeration and also informed limitations in advance.

Solar energy is free, abundant, and pollution-free fuel. If on the earth, instead of receiving the solar radiation which just heats the environment, some simple boxes (solar cookers) are placed, the food will be cooked and the environment will be more comfortable.

Even if only 5% of the population facing fuel shortage (25 million families) use solar ovens, roughly, the emission of 40 million tons of carbon dioxide per year will be prevented. Moreover, saving conventional fuels reduces the emissions of other pollutants.

Solar ovens are thus economically and ecologically viable.

Future Directions

In order to promote the use of solar energy and, in particular, solar cookers, various steps should be considered like:

- The design of the solar cooker should be appropriate for the needs of the people considering their cultural and local food habits.
- Both commercial and DIY models should be available.
- The buyers should be taught the proper uses of the solar cookers.
- The users should be informed clearly that the device is intended to save and not to substitute the conventional fuels, etc.

If taken into account these aspects, definitely, more persons both in rural and urban areas will use these devices for their personal benefit and for the planet.

Acknowledgments

The author is thankful to Solar Cookers International, Sacramento, CA, USA; the Abdus Salam International Center for Theoretical Physics, Trieste, Italy; Red Iberoamericana de Coccion Solar de Alimentos, Salta, Argentina; and Network on South South Cooperation on Renewable Energy Technology, Italy/England, for the invitation at their meetings, where good information was exchanged from participants of different countries for research and dissemination. The author is also thankful to Tec. Carlos Delgado for constructing some of these cookers.

Glossary

Air-conditioning Temperature and humidity control in buildings of each typology.

Coefficient of performance (COP) Factor which describes the ratio between useful and supplied energy.

Cooling Removing of heat.

Cost of saved primary energy Theoretical cost for 1 kWh of primary energy which is saved using an alternative system (e.g., driven by renewable energy sources) instead of a conventional one (only driven by fossil fuels or electricity from grid).

Demonstration project Organized implementation of a novel approach which aims at assessing the merits of widespread use of the approach and at gaining practical experience.

Primary energy saving Difference between the annual primary energy consumption of a conventional system which uses fossil fuels or electricity from grid and the annual primary energy consumption of a comparable system driven (partly) by renewable energy sources.

Sorption Exothermic process which comprises adsorption (a liquid or gaseous substance is attached to the surface of a solid, porous material) and absorption (a liquid or gaseous substance is taken in by a liquid volume).

Definition of the Subject and Its Importance

Cooling is needed for two main fields of application. On the one hand, it is needed in buildings and other closed spaces, for example, vehicles, which are occupied by human beings. Cooling assures that occupants feel comfortable. On the other hand, in industrial and commercial applications, cooling is needed to cool commodities or processes. In a wider sense, cooling in buildings refers to both control of temperature and control of humidity. In the following, it is referred to as *air-conditioning*. Cooling of commodities or processes is referred to as *refrigeration*. Cooling in a thermodynamic sense means to withdraw heat. Any heat flux is always directed from a source of high

temperature to a sink of lower temperature. Unless a natural heat sink is available – such as the ground or outside air – a thermodynamic cycle has to be employed in order to provide a low-temperature heat sink. *Solar cooling* means that a major part of the driving energy to operate such thermodynamic cycle is originating from the terrestrial solar radiation.

The first solar cooling installation has been developed by Augustin Mouchot and was presented at the World Exhibition in Paris in 1878 [39]. This system consisted of a concentrating solar collector in which solar radiation was converted into heat. The heat was used in an absorption cycle to produce ice. However, this process did not receive any economic importance for almost 100 years due to the development of electrically driven vapor compression systems and the increasing availability of cheap electricity to operate such systems. In the 1980s of the last century, similar processes – solar heat–driven cooling – received new attention mainly in the USA and in Japan [30]. Increasing energy prices after the oil price shocks led to a recollection of the possibility to make use of the sun's energy to provide cooling. Today, various heat-driven cooling technologies can be used in combination with heat which is generated in solar collectors. An alternative approach is to convert solar radiation into electricity by the application of photovoltaic modules and then to use this electricity to operate a vapor compression machine.

Introduction

Solar cooling has achieved more and more attention in particular in the twenty-first century. The main reasons were the rising prices of conventional, finite energies, an increasing awareness of environmental problems due to energy consumption and due to use of conventional refrigerants employed in vapor compression cycles, and a growing wish to use clean technologies for covering the energy demand in buildings. In the first decade of the twenty-first century, numerous pilot solar cooling installations have been built worldwide, particularly in Europe. Also, thermally driven cooling technologies were further developed to increase their efficiency, reduce their costs, and make them available in small capacity ranges.

This chapter starts with a brief overview on the physical principles which underlie the conversion of solar radiation into useful cooling. The discussion of the thermodynamic limits leads to a classification of different types of thermally driven cooling cycles in relation to the corresponding solar collector technology section ("Physical Principles"). Dominating technologies and system components are described technically and economically in more detail in sections "Common System Designs" and "Energy and Cost Performance." The section "System Experiences" presents overall systems including a few examples of existing installations. Finally, section "Future Directions" provides an outlook and outlines the perspectives and limits of solar cooling technologies.

Despite the fact that common cooling technologies and solar or solar-assisted systems, which are described in sections "Physical Principles" and "Common System Designs," are worth considering for several applications, for example, food conservation or industrial processes, this chapter mainly focuses on comfort cooling in buildings.

Physical Principles

This section covers physical principles of the conversion of solar radiation energy into useful cooling. After a brief presentation of the different conversion chains, a thermodynamic analysis is carried out which helps to classify different solar cooling systems in terms of efficiency and temperature.

Conversion Chains

Figure 1 shows the different conversion chains for the conversion of solar radiation energy into useful cooling.

A general distinction has to be made between systems driven by electric energy and systems driven by thermal energy (heat).

Photovoltaic modules (PV modules) are used to convert solar radiation into electric energy. In principle, any kind of electrically driven cooling devices can be used to produce useful cooling. The two main important systems are:

- Vapor compression cycle: mechanical vapor compression is the most common way of cold production. Electric engines are used to convert electricity into mechanical energy (mainly rotation) and for the compression of the refrigerant in the gas phase. Many different types of compressors are used for

Solar Cooling Systems. Figure 1
Conversion chains for the conversion of solar radiation energy into useful cooling

different technical applications. To employ photovoltaic modules for operation of a vapor compression cycle, an inverter normally has to be employed which converts the DC (direct current) electricity of the PV module into AC (alternating current) electricity which is needed by the electric engine. Today, PV-coupled vapor compression systems are mainly used in small-scale cooling devices such as refrigerators to conserve medicine or food in remote areas. In the future, cooling systems using PV modules connected to vapor compression chillers may play an important role even in other applications for refrigeration and air-conditioning. However, as long as the PV modules are connected to a public grid and feed the produced electricity into this grid, this combination should not be called solar cooling system because no direct coupling between PV modules and cooling device exists.

- Peltier cooling: the Peltier effect is a thermoelectric phenomenon which occurs when two materials with a different electric conductivity are connected. This principle can be used to produce cooling at the contact surface between two materials by inducing an electric current in the closed circuit. The efficiency is relatively low (approximately 3–8%). Therefore, this concept plays only a minor role in technical application, for instance in small transportable cooling devices for medicine.

Solar collectors are used to convert solar radiation energy into heat. The achievable temperature level depends on the type of used solar collector. For a detailed description of existing collectors and solar thermal systems, please see the chapters "► Solar Collectors, Non-concentrating," "► Linear Fresnel Collectors," and "► Parabolic Trough Solar Technology." Solar heat can be used to operate thermally driven cooling devices. A main distinction can be made between closed thermodynamic cycles which produce cooling and open cycles which are typically used for cooling and dehumidification of ventilation air. In machines using closed cycles the cold is typically transferred to the load using water as heat transfer fluid as long as temperatures above the freezing point of water are sufficient. Water-glycol mixtures are in use (antifreeze) when temperatures below 0°C are needed.

Today, the most dominating thermally driven cooling techniques are based on sorption technology using either liquid or solid sorption materials in open or closed cycles.

Therefore, the physical principles of the underlying processes are briefly described here. A detailed description of existing technical systems follows in section "Common System Designs."

Sorption refers to either absorption or adsorption. Absorption means the mixing of two substances, namely liquid absorbent and another liquid or vaporous material, without chemical reaction. Adsorption is the physical addition of a liquid or gas onto the surface of a solid material mainly by van der Waals forces and capillary condensation.

Absorption describes the incorporation or solving of a liquid or gas by the volume of another liquid material without chemical reaction. The two materials have an affinity for each other. Mixing of two materials with an affinity for each other is normally an exothermic process because heat of solution is released. Liquid or vaporous atoms or molecules "migrate" into the absorbent material by diffusion. The migration stops as soon as the solubility of the migrating material in the absorbent material is reached. This state is a dynamic equilibrium depending on the temperature level. Absorbent and absorbed material can be dissolved by heat treatment.

Adsorption describes a two-step energy conversion. In the first step, a volatile compound is bound by a solid adsorbent after diffusing in the pores of the solid material. This is an exothermic process. In the second step, the bound compound is driven off by heat. The binding of the molecules to the adsorbent is achieved by means of several forces but has to be fully reversible for technical applications. To optimize the adsorptive effect and the amount of adsorbed particles per volume of adsorbent, adsorbents should be of highly porous materials with a large internal surface. During the adsorption process, first, a monomolecular layer is formed on this surface by the molecules of the vaporous material due to van der Waals forces and electrostatic attraction [43]. After the monolayer is completed within the pores of the adsorbent, a liquefaction of the vapor takes place, and the liquid is further adsorbed by capillary condensation.

Beside techniques based on sorption, various other phenomena can be used for the transformation of heat into cooling. The most important one is the ejector technology. In an ejector cycle, the low-pressure refrigerant (e.g., water) is driven by fluid kinetic or thermal energy. The driving heat is utilized to convert water to superheated steam and this steam is accelerated in a nozzle. The produced steam is utilized by a steady-stream ejector to compress a secondary water stream. This secondary water stream evaporates in the evaporator and thereby produces the cooling effect. Also other fluids can be employed as refrigerants but using water allows a direct connection to the hydraulic network. Various other thermomechanical systems for thermally driven cold production are possible. Most straightforward is the operation of a Rankine cycle to produce mechanical energy from heat and to convert this mechanical energy (mainly rotation) into cooling using vapor compression systems. Such approach involves many different machines and is therefore only viable in large capacity systems. Since typically the level of temperature of the solar field is limited, organic Rankine cycles have to be used. Another thermodynamic machine which allows a directly heat-driven cooling is the Vuilleumier cycle which consists basically of an integrated direct coupling of two Stirling cycles operating in different directions.

Thermodynamic Analysis of Thermally Driven Chillers

A basic figure to describe the quality of the conversion of heat into cold is the thermal Coefficient of Performance COP, defined as the useful cold Q_{cold} per unit of invested driving heat Q_{heat}, see Eq. 1:

$$COP = \frac{Q_{cold}}{Q_{heat}} \tag{1}$$

The first and second law of thermodynamics applied to the basic process of a thermally driven chiller, according to the scheme shown in Fig. 2, lead to an equation for the upper limit of the Coefficient of Performance, COP_{ideal}, in which the COP is only dependent of the three governing temperature levels (all temperatures in Kelvin, K), see Eq. 2:

$$COP_{ideal} = \left(\frac{Q_{cold}}{Q_{heat}}\right)_{ideal} = \frac{T_c}{T_h} \cdot \frac{T_h - T_m}{T_m - T_c} \tag{2}$$

where T_c is the temperature of the cold source (useful cooling), T_h is the temperature of the driving heat source, and T_m is the intermediate temperature level at which the heat is rejected to a heat sink (in most

Solar Cooling Systems. Figure 2
Basic scheme of a thermally driven cooling cycle with the three dominating temperature levels

cases, this heat sink is environmental air using either a wet cooling tower or a dry air cooling tower; see also section "Subsystems and Further Equipment Components"), see Fig. 2.

The COP_{ideal} calculated according to Eq. 2 gives the upper thermodynamic limit which can never be achieved in practice. Real COP values of thermally driven chillers range between 0.6 for systems which work with low driving temperatures starting at about 60°C and 2.0 for a recently newly developed machine [53] which operates with driving temperatures above 200°C. Common systems, which will be described in more detail in section "Common System Designs," are characterized by COP values of 0.7 up to 1.2.

The fraction between real COP, COP_{real}, and maximum COP, COP_{ideal}, at the same conditions, is called Carnot Efficiency Factor ξ_{Carnot} and is given by Eq. 3:

$$\xi_{Carnot} = \frac{COP_{real}}{COP_{ideal}} \tag{3}$$

The Carnot Efficiency Factor can never exceed 1 and has a value which lies significantly below 1 for any real technical system. This factor is a single number that expresses all irreversibility within a thermodynamic machine. Its value lies in the range of 0.25–0.35 for common thermally driven cooling systems available on the market. The ξ_{Carnot} can be increased by different measures which lead to a reduction of entropy production such as improved heat recovery in the internal cycle, increased heat exchanger areas, measures for enhanced mass transfer, and others.

The task for any cooling process is to create a temperature difference between the heat flux entering the thermodynamic machine at low temperature T_c and a heat flux leaving the thermodynamic machine at medium temperature T_m. This temperature difference is called temperature lift Δ:

$$\Delta = T_m - T_c \tag{4}$$

The higher the temperature lift, the higher the thermodynamic effort.

Combination of Eqs. 2, 3 and 4 leads to an equation for the needed driving temperature $T_{h,needed}$ as a function of the temperature lift Δ, including given Carnot Efficiency Factor ξ_{Carnot} and given COP_{real} of the machine:

$$T_{h,needed} = \frac{T_c + \Delta}{1 - \frac{COP_{real} \cdot \Delta}{\xi_{Carnot} \cdot T_c}} \tag{5}$$

Figure 3 highlights the dependence of the needed driving heat temperature on the COP, ξ_{Carnot}, and the temperature lift. Four different lines show exemplary COP values of 0.75 and 1.2 combined with Carnot Efficiency Factors of 0.3 and 0.4. The typical operation temperature ranges of different solar collector technologies are marked, and different ranges of the temperature lift Δ are characterized. Several types of fixed and tracking solar collectors which can be used as driving source of cooling systems are described in other chapters; see "▶ Solar Collectors, non-concentrating," "▶ Linear Fresnel Collectors," and "▶ Parabolic Trough Solar Technology."

The required temperature lift is a basic value in the design phase of a (solar or solar-assisted) cooling system. In Table 1 various possible system examples are shown and the temperature levels for cooling and heat rejection using different technical solutions are described. Together with the analysis of Fig. 3, Table 1 allows a rough selection of a possible solar collector technology which is suitable for a specific system.

Typical applications and examples of systems are:

- In case of a low-energy cooling system, that is a system which can be operated with a low

Solar Cooling Systems. Figure 3
Needed heat source temperature as a function of the temperature lift for different COP/ξ_{Carnot} combinations

Solar Cooling Systems. Table 1 Overview on different solar cooling systems characterized by the required temperature lift; only configurations for which market available solutions exist are shown

	Temperature lift	Low (10–15 K)	Medium (15–30 K)		High (30–45 K)	Very high (>45 K)
	Supply temperature (room system in case of comfort A/C)	15–20°C, e.g., chilled ceiling, floor cooling, radiative cooling	15–20°C, e.g., chilled ceiling, floor cooling, radiative cooling	6–12°C, e.g., fan coil, AHU with dehumidification	6–12°C, e.g., fan coil, AHU with dehumidification	<0°C, e.g., ice production, ice storage
	Reject temperature, reject system	25–30°C wet cooling tower; ground	35–45°C dry cooling tower	25–30°C wet cooling tower; ground	35–45°C dry cooling tower	35–50°C dry cooling tower
Low COP technology	**Driving temperature range**	70–85°C	85–110°C	85–110°C	100–130°C	180–250°C
	Possible solar collector types	Efficient, fixed	Efficient to highly efficient, fixed	Efficient to highly efficient, fixed	Highly efficient, fixed; single-axis tracking	Single-axis tracking
High COP technology	**Driving temperature range**	*No market available cooling system for this configuration*	130–200°C	130–200°C	200–300°C	*No market available cooling system for this configuration*
	Possible solar collector types		Single-axis tracking	Single-axis tracking	Single-axis tracking	

temperature difference between room temperature and temperature of cold water such as a chilled ceiling (or more generally radiative cooling), a low temperature lift in the range of 15 K is sufficient, at least in moderate climates and when a wet cooling tower is used. Such systems can be operated using cooling machines (see section "Common System Designs") driven by heat at moderate temperatures which is generated in normal efficient, fixed solar collectors, that is solar collectors that do not have to be tracked to the sun's direct radiation.

- The same system as described above but using a dry cooling tower works with a higher temperature lift in the range of 15–30 K because the temperature level for heat rejection is higher. In this case, there are also cooling machines which can be operated at a higher thermal COP (double-effect chillers; see section "Common System Designs"). Correspondingly, another solar collector technology has to be employed in order to provide the needed higher driving temperature.
- A common fan-coil system in which dehumidification is realized by cooling the air below the dew point needs chilled water in the range of 6–8°C. With a temperature for heat rejection in the range of 25–35°C a temperature lift of about 20–30 K is necessary. For such a system, very highly efficient flat-plate collectors or evacuated tube collectors are necessary in case cooling machines with low COP value are used. For cooling machines with high COP values, high-efficiency evacuated tube collectors can possibly be employed but in most cases solar collector systems with optical concentration which are tracking the sun are necessary.
- Under conditions of high ambient air temperatures (>35°C) and when wet cooling towers cannot be employed (e.g., due to high wet-bulb temperatures or no availability of water), a high temperature lift above 30 K will be necessary. This is even more valid if a low temperature on the cold side is needed, for example in case of ice production or using an ice storage to overcome mismatches between cooling load and solar gains because then the temperature lift can even exceed 45°C. In this latter case, only a machine with low COP value can be used if driving temperatures up to 300°C are available. Therefore a solar collector system with optical concentration will be necessary. These conditions correspond to the needs in hot, arid regions in which fresh water is costly or a scarce commodity.

Figure 3 also indicates that, in principle, two tracks are possible in order to improve the efficiency of solar cooling systems. On the one hand, using a highly efficient solar collector allows higher driving temperatures and thus an increased COP. On the other hand, an increase in the Carnot Efficiency Factor allows operation of a thermally driven chiller at lower operation temperatures. Both tracks are subject of ongoing R&D activities.

An overview on the COP values of most common closed cycle heat-driven chillers is given in Fig. 4.

Common System Designs

One of the main reasons for the application of solar cooling is to replace common compression chillers for which electrical energy is required to drive the compressor by technologies using renewable energies. Solar cooling systems are based on different technical designs. Therefore, it makes sense to divide the mainly applied technologies into closed systems: mainly absorption chiller and adsorption chiller, and open systems: desiccant evaporative cooling (DEC) systems and liquid desiccant air-conditioning (LDAC) systems. Absorption and adsorption chillers are used for cooling; desiccant systems are used for air-conditioning: cooling and dehumidification. Absorption chillers are the most widespread-used solar-driven chillers with a current share in realized installations of about 71%. The corresponding share of solar-driven adsorption chillers is 13%, of DEC systems 14%, and of LDAC systems 2% [21].

A diagram of a common vapor compression system is shown in Fig. 5, with the main components evaporator, condenser, and compressor. The simplified principle of the cold production can be explained as follows: liquid refrigerant evaporates under low pressure and low temperature, extracting heat from the system to be cooled. Refrigerant vapor is compressed to higher pressure, condenses at a higher temperature, and thereby releases heat which needs to be rejected. Subsequently, the pressure of the liquid refrigerant is reduced by expansion through a throttle valve, and the cycle is repeated [15].

Solar Cooling Systems. Figure 4
Typical COP curves of sorption chillers and the upper thermodynamic limit (ideal) according to Eq. 5

Solar Cooling Systems. Figure 5
Scheme of a vapor compression system in which an electrically driven compressor is used

Closed Absorption Systems

The development of absorption processes for applications in refrigeration dates back to the eighteenth century. In 1777, G. Nairne observed the absorptivity of concentrated sulfuric acid in water which is considered as the starting point of absorption technology [52]. Another father of absorption technology is F. Carré. He presented a patent of the first absorption cooling machine based on the working pair ammonia/water in 1859. At the same time, W. Thomson (better known as Lord Kelvin) presented the concept of a heat pump to make use of the waste heat of a refrigerator for heating purposes [34, 49, 53]. In his work, he described different combinations of compression and expansion cylinders for heating and cooling applications.

In absorption systems, the mechanical compressor is replaced by a "thermal compressor" existing of absorber, desorber (generator) and solution pump, see Fig. 6. In contrast to mechanical compression, the main driving power to the generator is not provided by mechanical energy (or electrical energy in combination with an electric engine, respectively) but by heat using a low-temperature heat source, for example solar collector, district heating, or waste heat. The solution pump needs only little mechanical (electrical) energy since it has only to increase the pressure of a liquid and not of a gas like in a vapor compression cycle. Further, main components are the evaporator, the condenser and the throttle valves used for expansion.

Absorption chillers can be divided into different types. They are continuously working closed cycle systems but occur as single-effect, double-effect, triple-effect, or double-lift systems or as systems combining different designs, for example single-effect/double-lift (SE/DL) systems. More detailed descriptions of the different systems follow later in this section. Installation differences lie furthermore in the utilized heat source for the generator.

The operating media determines the operating temperature level. The medium used as refrigerant depends on the needed temperature of the useful cooling.

Solar Cooling Systems. Figure 6
Scheme of an absorption system for cooling

For cooling applications with a temperature level above the freezing point of water (273.16 K/0°C), often water (H_2O) is used as refrigerant, and a solution of water and lithium bromide (LiBr) is used as sorbent. For cooling applications with a temperature level below the freezing point of water, in most cases ammonia/water (NH_3/H_2O) is used as working pair; here, ammonia is the refrigerant and water the sorbent. For comfort air-conditioning temperatures above 0°C are sufficient [53].

The refrigerant/absorbent working pair H_2O/LiBr was first developed by the Carrier Company which constructed a laboratory prototype in 1942 which was first distributed in 1944 in the USA [49].

Process and system technology can be explained best by showing a standard single-effect system. Such a system consists of the following main components: evaporator, absorber, desorber, and condenser.

Since the *evaporator* is responsible for the cold production, the process cycle is explained by starting from this point. The working point at this place is determined by the saturation line of the pure refrigerant. Consequently, the less pressure exists, the less temperature is necessary to evaporate the liquid refrigerant. The refrigerant (e.g., water) which is fed in the low-pressure evaporator is evaporated at low temperature by extracting heat from the heat source which thereby cools down. This step represents the desired cooling effect.

The refrigerant vapor migrates to the *absorber* which operates also at low pressure and is continuously absorbed by a suitable liquid solvent (e.g., LiBr) and condenses. This results in a liquid solution with heat release (exothermic process). The heat produced in this process step has to be withdrawn continuously (by an external circuit) in order to extract the heat of condensation and binding and thus to keep the absorption process ongoing. The lower-boiling component functions as refrigerant (water), the high-boiling component functions as absorbent (LiBr solution). The advantage is that not the pressure of gas but of liquid has to be increased, and the driving power is significantly lower than that of compression systems [37]. The weak solution which is pumped to the desorber flows through a heat exchanger device and is preheated; as a consequence, both pressure and temperature rise. A solution heat exchanger is not necessarily needed for an absorption system but helps to reduce the required desorption heat due to preheating the weak solution. For this purpose, the heat is taken from the back-flowing rich solution (LiBr), which passes the heat exchanger from its way back from desorber to absorber.

In the *desorber* the weak solution is heated further and the refrigerant evaporates at a higher pressure level. Nonmechanical work serves as driving energy of the chiller but heat at a temperature level of about 80–200°C depending on the thermodynamic design.

Solar Cooling Systems. Figure 7
Schematic picture of an absorption system for cooling depicting solution with refrigerant cycle and solution heat exchanger

Driving heat is supplied by an external heat source such as waste heat of an industrial process or a cogeneration unit or heat from a solar thermal collector. The refrigerant vapor migrates to the condenser. The reconcentrated rich solution is led back to the absorber and thereby passes the other side of the solution heat exchanger. Heat is transferred to the counterflowing weak solution, and the temperature of the rich solution decreases. The liquid absorbent is expanded through a throttle valve from high to low pressure. The solution cycle is closed when the rich solution reenters the absorber.

Following up the refrigerant cycle the refrigerant (e.g., water) vapor flows to the *condenser* and condenses through the application of cooling water at the same pressure level as the desorber. Liquid refrigerant circulates back into the *evaporator*. Being expanded by a throttle valve the liquefied cooling agent cools down on its way back to the evaporator. The cycle restarts at a low pressure and temperature level [8, 15, 49].

For a better understanding, see Fig. 7 which shows schematically refrigerant and solvent cycle, Fig. 8 which shows schematically the pressure and temperature levels of the corresponding single-effect absorption process (with E as evaporator, A as absorber, D as desorber, and C as condenser) and Fig. 9 which shows the corresponding ln p-x and ln p-(1/t)-diagram of a single-effect absorption with water/LiBr.

Solar Cooling Systems. Figure 8
Scheme of pressure and temperature levels of a single-effect absorption process

An essential part of the system is the source of driving heat (for the desorber). Possible heat sources are, for example, industrial waste heat, heat supplied by a thermal power station or district heating system, gas or oil firing and exhaust gas of motors, fuel cells, and turbines (cogeneration). Solar cooling systems are – completely or predominantly – driven by heat provided by solar collectors [6]. For details on solar collectors, please have a look at the following chapters in this

Solar Cooling Systems. Figure 9
ln p-x and ln p-(1/T)-diagram of a single-effect absorption process with water/LiBr

Solar Cooling Systems. Figure 10
Scheme of pressure and temperature levels of a double-effect absorption cooling process

book: "► Solar Collectors, non-concentrating," "► Linear Fresnel Collectors," and "► Parabolic Trough Solar Technology."

A double-effect machine has a second desorber (generator) and a second condenser which works at a higher pressure and temperature level, see Fig. 10. The rejected heat of the condenser working at high pressure and temperature drives the desorber at the first stage. Generally, the second desorber is driven either directly by a natural gas or oil burner or indirectly by supplying steam or pressurized water at high temperature level. If solar energy shall be used to drive such systems, solar collectors working at high operation temperatures have to be used. Heat is added to the generator of the top cycle (primary generator) which generates refrigerant vapor at a higher temperature and pressure relatively to the bottom cycle. The vapor is then condensed at this higher temperature and pressure and the heat of condensation is used to drive the generator of the lower cycle (secondary generator) which is at a lower temperature. Double-effect cycles have a higher COP than single-effect cycles but need

higher driving temperatures for their operation. The COP can be up to one, two [10], or slightly above, and typical driving temperatures lie in the range of 140–160°C. Current research is concentrating on three and four effect systems, which present an attractive potential for improved cooling performance, with a COP of 1.7–2.2, but these systems require a distinctly higher temperature of driving heat [15].

Single-effect and double-effect cycles as described above are the most common designs of liquid absorption systems. However, various other design options exist which aim at adjustment of the cycle to special boundary conditions. Double-lift cycles are for instance used to allow lower driving temperatures. For double-lift systems NH_3/H_2O solutions are typically used [10]. A double-lift machine has a second absorber and a second desorber, see Fig. 11. Compared to a single-effect machine a lower driving temperature is needed. The second absorber is used to absorb the refrigerant vapor generated in the first generator and the second generator produces pure refrigerant vapor which condenses in the condenser. Overall, more heat at lower temperature level is needed compared to a single-effect cycle and thus lower COP results. A combination of a single-effect and a double-lift cycle is called single-effect/double-lift (SE-DL), see Fig. 12 [10]. It requires a driving heat temperature similar to a single-effect system but allows a large temperature spread along the driving heat circuit. This is an advantage for many driving heat sources which need a sufficiently high-temperature spread such as for instance combined heat and power systems. A detailed description of these cycles and discussion of alternative working pairs can be found in [35].

Table 2 provides a short overview on the COP values of the different types of absorption system designs. The COP values reported in literature differ and the ranges given in Table 2 correspond to the lowest and highest values reported.

Typical chilling capacities of absorption chillers are above 100 kW up to MWs. Since a few years, several single-effect absorption chillers with capacities below 50 kW are available. For instance, a water/LiBr chiller which has been newly developed for small capacities (nominal capacity 10 kW) enables part-load operation with reduced chilling power at a heat source temperature of 65°C and a COP of still approximately 0.7. This is very promising in combination with a solar

Solar Cooling Systems. Table 2 Overview on typical temperature levels of closed cycle absorption chillers, values from [18, 29, 42, 46]

Closed cycle system	Single effect (H_2O/LiBr)	Double effect (H_2O/LiBr)	Single effect/Double lift (H_2O/LiBr)	Double lift (NH_3/H_2O)
Cold temperature [°C]	6. . .20	6. . .20	6. . .20	−50. . .20
Heating temperature [°C]	70. . .110	130. . .160	65. . .100	55. . .65
Cooling water temperature [°C]	26. . .35	26. . .35	30. . .35	30. . .35
COP [−]	0.5. . .0.8	0.9. . .1.3	0.4. . .0.7	0.4

heat source and shows the high potential for performance improvements of absorption chillers. The new medium-sized and small-sized developments have been designed recently by European and Asian manufacturers, convenient to cover the cooling loads of small buildings with floor areas in the range from 150 to 500 m^2. The European manufacturers are located in various countries and many of the new developments are still being tested in pilot installations.

In Germany, in 2000, only 10% up to 30% of absorption chillers were estimated to be double-effect systems [41]. The reason may be that the system cannot work with low-temperature heat and hence is inappropriate for combined heating, cooling and power (CHPC) applications, comes along with high invest costs, and needs high driving temperature. The need for higher driving temperatures also makes double-effect chillers less suitable for solar-assisted air-conditioning systems using common solar collectors. However, it is possible to use high-temperature solar collectors such as single-axis tracking concentrating solar collectors. These systems need a high fraction of direct solar radiation since optical concentration with mirror or lens systems requires direct radiation while the diffuse radiation cannot be used [15].

Closed Adsorption Systems

Process and system technology of adsorptive cooling is similar to that of absorptive cooling regarding main components and the production of the useful cooling effect but differ in respect of its system design. Adsorption systems combine the system components evaporator, condenser and "compression technology": sorption,

desorption and heat source. The sorption process is performed under vacuum by an adsorber with solid adsorbent which hence cannot be circulated through the system. Adsorption is a quasi-static batch process. By making use of more than one adsorber, a periodic, quasi-continuous operation is possible. Typically, two adsorbers are used and operated in an alternating way. The four resulting components are arranged as a four chamber system linked by valves, see Fig. 13.

Like in absorption systems the main driving power is not provided by electrical energy but is replaced by a heat source and the refrigerant compression is performed by an ad- and desorption process. The medium used as refrigerant is often water. Typical working pairs are water/silica gel and water/zeolite. Also, ammonia/activated carbon, ammonia/zeolite, or methanol/activated carbon are possible working pairs. For applications in the field of cooling only machines using silica gel or zeolite as adsorbent and water as refrigerant are currently available on the market [15]. Silica gel is highly porous and hydrophilic and possesses an extensive surface in its interior.

Since the evaporator is responsible for the cold production and is therefore the main part of the system, the process cycle is explained starting from here.

The less pressure exists, the less temperature is necessary to evaporate liquid. The refrigerant (e.g., water) which is fed in the *evaporator* evaporates at low temperature and extracts heat from a warmer source which thereby cools down. This is the useful cooling effect.

The refrigerant vapor migrates to one of the *adsorber* chambers, namely the one which is cooled and has a low refrigerant loading. The refrigerant vapor is adsorbed on the inner surface in the pores of the solid adsorbent. The heat produced in this process step by condensation and binding of the refrigerant has to be removed by the cooling water system. The colder the adsorbent the more refrigerant (water) can be adsorbed.

At the same time, the refrigerant (water) is driven off the adsorbent by the use of heat in the other chamber which now function as *desorber* (generator). Heat is supplied by an external hydraulic circuit and is transferred to the sorption material by a heat exchanger. The vaporous refrigerant migrates to the condenser and condenses through rejecting heat to the cooling water system. Liquefied refrigerant is led back to the evaporator through a throttle (e.g. formed as a U-pipe).

The adsorption process in the adsorption chamber is operated until a refrigerant loading close to the

Solar Cooling Systems. Figure 13
Scheme of an adsorption system for cooling

equilibrium at given temperature conditions is achieved. Similarly, the desorption process in the desorption chamber is operated until almost no more refrigerant is released at given temperature conditions. Now, the functions of the chambers interchange. This interchange phase can be realized with heat recovery. Heat recovery enables preheating of the chamber which is switched from adsorption to desorption and vice versa precooling of the other chamber.

The second period starts: the regenerated adsorbent in the previous desorption chamber – which now functions as adsorption chamber – adsorbs vaporous refrigerant and the previous adsorption chamber functions as desorption chamber; the refrigerant is driven off the adsorbent [1, 45]. Figure 14 depicts schematically the whole adsorption process in four stages which allow a quasi-continuous operation.

For further understanding, the pressure and temperature profiles of an ideal adsorption process for one chamber is explained in detail in the following, see also Fig. 15.

There are two pressure levels: that of the evaporator and that of the condenser whereby that of the evaporator is lower. Before the adsorption process starts, the adsorption chamber, with both valves closed, is cooled down until the pressure level of the evaporator is reached. At the beginning of the adsorption process, the valve to the evaporator opens. This valve could be controlled either mechanically and based on an external control or can be an automatic valve which simply follows the pressure difference that is created by the temperature conditions. The low-temperature refrigerant (e.g., water vapor) enters the adsorption chamber and is adsorbed by the adsorbent (e.g., silica gel). Since

Solar Cooling Systems. Figure 14
Scheme of an adsorption process in four stages which allows a quasi-continuous operation

Solar Cooling Systems. Figure 15
Scheme of pressure and temperature cycle of an adsorption system for cooling

this process is exothermal, heat has to be removed continuously. As soon as the refrigerant loading of the adsorbent is close to the equilibrium loading at given temperatures, further adsorption and evaporation diminishes. The valve to the evaporator closes, and heating of the chamber begins. The pressure rises to the pressure of the condenser. The valve to the condenser opens and under constant pressure and rising temperature the refrigerant is driven off. The desorption process ends at desorption end temperature, namely the highest temperature that occurs in the cycle which is defined by the available temperature of the external heat source. The valve to the condenser closes and the adsorption chamber is cooled down again [4, 11, 18].

The driving heat to the process is typically supplied by waste heat from industrial processes or a combined heat and power system, district heating, or solar energy. As adsorption systems already start working at temperatures of about 55°C. Different solar collectors can be used, such as vacuum tube solar collectors or flat-plate collectors [51]. Solar collectors are explained in detail in the following chapters: "► Solar Collectors, non-concentrating," "► Linear Fresnel Collectors," and "► Parabolic Trough Solar Technology."

Adsorption cooling systems are produced by few manufacturers in Asia and, recently, Europe. The simple mechanical construction and robustness of adsorption chillers is an advantage. Further positive facts are the minimized electricity demand, the possibility to work at low driving temperatures and that there is no risk of crystallization as is in the case of using water/LiBr absorption chillers. Adsorption chillers show two main disadvantages: the periodic nature of the process reduces the potential for heat recovery in comparison to system employing liquid sorption materials, and the used sorption materials usually have very low thermal conductivity. As a result, adsorption systems have somewhat lower COP values and a larger volume compared to absorption systems [17, 18].

Another disadvantage is that the periodic process leads to temperature fluctuations on all temperature levels and, in particular, on the driving heat side, see Fig. 16. The figure shows an excerpt of monitoring data of an installed plant. These fluctuations have to be taken into consideration in the hydraulic design of a cooling system using adsorption technology. One possibility to reduce the impact of the fluctuations is the in-series installation of a small buffer on the return line of the heating cycle of the adsorption chiller.

Recent research work focuses on overcoming the disadvantages of the adsorber's large needed volume and weight by developing advanced heat exchanger

Solar Cooling Systems. Figure 16
Excerpt of monitoring data of an installed adsorption chiller plant

constructions with enhanced heat and mass transfer and thus reduced volume and weight.

Open Solid Desiccant Systems

Desiccant systems cannot only serve for cooling but also for control of humidity and are thus air-conditioning systems. The aim is to provide rooms and other closed spaces with dehumidified and cool air and thereby to ensure comfortable indoor climate conditions.

In desiccant systems, air is treated in an open sorptive cooling cycle where the sensible and latent functions are separated. In principle, warm and moist fresh air is dehumidified by a desiccant and then cooled by sensible heat exchange. If the humidity ratio behind the desiccant component is low enough, direct evaporative cooling may be used for lowering the temperature of the air. A desiccant is a material with a strong attraction for water vapor, classified as either solid or liquid depending on its normal physical state. In desiccant air-conditioning systems silica gel and lithium chloride (LiCl) are typically used desiccants. LiCl can absorb water vapor both either as a solid, hydrated salt, or as an aqueous solution. Further desiccants which might be employed in desiccant air-conditioning are calcium chloride ($CaCl_2$), activated carbon, zeolites, and LiBr.

Although all common desiccant cooling systems include at least the three major components sorption device, evaporative cooler (indirect, direct, or both), and sensible heat exchanger, many different configurations and technical designs exist.

Differences depend on various aspects:

- For the sorption process, solid or liquid desiccants can be used.
- The sorptive dehumidification can be realized as an adiabatic or nonadiabatic process.
- Depending on climatic conditions and desired supply air conditions, a desiccant process can be designed in combination with a conventional air-handling process using vapor compression cooling devices.
- Evaporative cooling may be used in a direct way, in an indirect way, or in both direct and indirect way. This depends on climatic conditions [17].

To explain the DEC process in detail, a typical standard installation using a rotor type desiccant wheel for applications in temperate climate zones is described. Main components are air filter, desiccant component, heat recovery device, evaporation humidifier, fans, and air heater [40]. The desiccant is regenerated by heat. This can for instance be achieved with solar energy. A schematic representation of a typical DEC installation is shown in Fig. 17. The technical design includes two interacting airstreams (Fig. 17: bottom: fresh/supply air and top: return/exhaust air), flowing in opposite directions.

Solar Cooling Systems. Figure 17
Scheme of a DEC system for air-conditioning in temperate climate conditions; the lower heat supply is only used for heating conditions

Solar Cooling Systems. Figure 18
Picture of a standard solid desiccant cooling system for applications in temperate climate zones (Source: Munters GmbH)

As solid desiccant component serves a rotating sorption wheel equipped with sorption material (in most cases silica gel or LiCl). Figure 18 shows a picture of a DEC installation, named DesiCool, of the company Munters GmbH.

The steps to describe the DEC process are explained in detail in the following; additionally, please see the T-x-diagram in Fig. 19.

Process steps on supply air side [9, 15, 20]:

(1) Fresh, warm and moist air enters the system from outside and first flows through a filter. Temperature and humidity at this state are equal to outside air conditions.
(1) ➔ (2) The sorption wheel rotates slowly (typically 8–12 rotations per hour). The air passes into the wheel and is dehumidified by the desiccant because the water vapor is adsorbed by the desiccant material. The temperature of the dehumidified air rises through the adsorption and by being heated from the hot thermal mass of the desiccant wheel. The process is almost adiabatic.
(2) ➔ (3) Warm and dehumidified air passes into the heat recovery unit (heat recovery wheel or plate heat exchanger) and heat is transferred to the colder air on the return air side.
(3) ➔ (4) The supply air, precooled and dehumidified, enters the humidifier. Incoming water evaporates and the needed heat is taken from the supply air which effects evaporative cooling. Different types of direct evaporative cooling devices can be employed such as air washers, spray nozzle humidifiers

Solar Cooling Systems. Figure 19

T-x-diagram of a DEC process in cooling operation for applications in moderate climate zones

(low or high pressure) or ultra-sonic devices. This component would not be employed in case of humid climatic conditions since the humidity at this position would not allow for the use of direct evaporative cooling.

(4) ➔ (5) In summer/cooling season: a small temperature increase caused by the fan leads to desired supply air conditions. In winter/heating season: the heating coil is operated for heating of the supply air to the desired room air conditions. Again a small

temperature increase occurs due to the fan's waste heat.

(5) ➔ (6) Air temperature and humidity are increased by means of internal loads.

Process steps on return air side:

(6) Return air leaves the conditioned space. Temperature and humidity depend on the place where the air is sucked from the room. If the air is taken from a level of building occupants, temperature and humidity correspond to the comfort room air conditions.

(6) ➔ (7) The air is cooled using evaporative cooling close to the saturation line intending to get close to the lowest possible temperature (wet-bulb temperature) and thereby to maximize the precooling of the supply air in the heat recovery unit.

(7) ➔ (8) In counterflow to the supply air the exhaust air is preheated, see process step (2) ➔ (3).

(8) ➔ (9) The exhaust air, humidified and preheated, flows through a heat exchanger device to be further heated by means of an external heat source. The heat can be provided by waste heat, a cogeneration plant, a combined heat and power (CHP) cycle, or solar energy. Either flat-plate collectors or solar air collectors are employed in case of solar energy-driven systems.

(9) ➔ (10) The hot air passes into the sorption wheel and regenerates the desiccant, see process step (1) ➔ (2), thereby the temperature of the exhaust air falls and the humidity ratio increases.

(10) ➔ (11) The exhaust air is blown to the environment by means of an air fan.

To adapt such a standard model to other climate conditions, several measures can be taken, for example adding a cooling coil behind the heat recovery wheel on the supply side, adding two cooling coils (one before the sorption wheel and a second behind the humidifier), or implementation of a second sorption wheel with a cooling coil before and a second cooling coil behind the heat recovery wheel [17]. Also, combinations of sorption wheels and enthalpy wheels can be used to obtain an increased reduction of the humidity ratio of ambient air.

One of the disadvantages of conventional evaporative sorptive cooling systems which use sorptive wheels to dehumidify the fresh air is that the air is not only dehumidified but also heats up. The released sorption heat leads to a temperature increase of the desiccant material which leads to a reduced dehumidification potential. This is due to the adiabatic characteristic of the sorption process and the fact that the sorption process is not cooled. Recent developments aim at cooling the sorption process in desiccant systems using solid sorptive materials. An example is the so-called ECOS process which has been developed at the Fraunhofer-Institute for Solar Energy Systems ISE in Freiburg/Germany. The acronym stands for indirect Evaporative COoling counterflow heat exchanger with Sorption. This system is particularly intended for climates with high ambient air humidity (e.g., tropical climates). The design of the ECOS process results in a far higher dehumidification potential in comparison to conventional systems [16].

The ECOS system bases on crossflow or counterflow air-to-air heat exchanger technology; see scheme in Fig. 20.

Process steps on supply air side:

(1) Fresh, warm, and moist air enters the system from outside.

(1) ➔ (2) The air flows through a heat exchanger to be cooled down and is dehumidified simultaneously by means of sorptive coated heat exchanger channels (green line in Fig. 20, top).

(2) ➔ (3) The supply air stream can optionally be further cooled down to meet specific load demands.

(3) ➔ (4) Air temperature and humidity of the air increase due to internal loads.

Process steps on return air side:

(4) ➔ (5) The return air is humidified and cools down.

(5) ➔ (6) The cool and humidified return air flows through the cooling channels (orange line in Fig. 20, top) at return air side of the heat exchanger which are physically separated but in close thermal contact to the supply side channels. In the cooling channels, the indirect evaporative cooling is obtained by a continuous humidification process ensuring a high heat exchange potential. The return air stream is humidified to close-to-saturated conditions during this process.

As soon as the sorptive material is enriched with water, the process is stopped. The heat exchanger is

Solar Cooling Systems. Figure 20
Scheme of the ECOS (Evaporative COoling counterflow heat exchanger with Sorption) system and process steps; the lower part shows one possible flow pattern for regeneration

regenerated (possible flow pattern shown in the red line in Fig. 20, bottom). In the regeneration phase, the water vapor load of the sorbent material is released to the environment by means of a hot air stream (60–95°C). Thereby, the heat exchanger heats up. After the regeneration, a precooling phase is performed to lower the temperature of the heat exchanger before it is again used for conditioning of fresh air.

Figure 21 shows the corresponding T-x-diagram of the ECOS process.

A complete air-conditioning system consists of two sorptive heat exchangers which operate periodically creating a quasi-continuous air-conditioning process. While one heat exchanger is used in air-conditioning operation mode, the other one is regenerated and precooled. After one operation phase, the functions are changed. Optionally, a humidifier can be installed on the supply air side in order to exploit the potential for direct evaporative cooling [16, 37, 38].

Open Liquid Desiccant Systems

Though liquid desiccants have been successfully working since a long time, there are only a few installations nowadays. Dr. Russell Bichowsky from Frigidaire Division of General Motors had used solutions of lithium chloride to dry air in the 1930s and sold the technology to Surface Combustion Corporation (SCC). A residential liquid-desiccant dehumidifier was developed by SCC, but no market introduction followed. Simultaneously, the Niagara Blower Company introduced a liquid desiccant technology that used glycol solutions to prevent frost formation on low-temperature evaporators. However, the development of air-conditioning systems went in another direction due to low prices for electricity and because, at those times, sustainability was not an issue. Nevertheless, in recent years, some liquid desiccant systems for comfort air-conditioning have been developed, have been tested in pilot installations and are now available on the market [31].

The design, process and utilized working fluids of open desiccative air-conditioning systems based on liquid sorbents (LDAC) differ from DEC systems. A schematic drawing of a possible general type of a desiccant system using liquid desiccant is shown in Fig. 22. Liquid desiccant technology uses absorption to dehumidify an air stream. The absorption process can be either cooled or operated adiabatic.

Desiccants have to be nonvolatile if they are used in air-conditioning systems. For example, halide salt solutions meet this requirement but, at the same time, are corrosive. The corrosiveness can be managed by either working with very low desiccant flow rates or using noncorrosive materials (e.g., based on polymers). In current systems typically hygroscopic aqueous salt solutions, for example calcium chloride/water, lithium bromide/water, or lithium chloride/water are used. A great advantage of such liquid desiccants is the

Solar Cooling Systems. Figure 21
T-x-diagram of the ECOS (Evaporative COoling counter-flow heat exchanger with Sorption) process

much higher energy storage capacity compared to solid materials.

The (warm and humid) fresh air enters the *absorption* chamber. The chamber in which the absorption process of LDAC systems takes places is realized either in a packed bed absorber filled with structured material (similar to the corrugated filling that might be used in a cooling tower), in other enhanced mass transfer surface or packing units, or in plate heat exchangers with a falling film regime of the liquid desiccant. Important

Solar Cooling Systems. Figure 22
Scheme of a desiccant air-conditioning system using liquid desiccant

is to ensure optimal heat and mass transfer between desiccant solution and air. The liquid desiccant is usually sprayed into the absorber chamber. The flow rate of the desiccant must be high enough to ensure complete wetting of the fill's surface [32]. The fresh air flows over the wet surface of the fill. When the desiccant absorbs water vapor from the air, heat will be released and the desiccant's temperature increases. The released heat includes the chemical heat of mixing between the desiccant and water, in addition to the vapor–liquid latent heat for the water vapor [33]. The dehumidification capacity depends both on the temperature of the absorption process and the concentration ratio of the desiccant solution which is sprayed in. In adiabatic systems a high flow rate of the desiccant limits its temperature rise to a few degrees. Cooled systems comprise a heat exchanger device to control the temperature of the process and therefore can be operated with a much lower flow rate of desiccant. The air leaves the absorption chamber, dehumidified and cooled, and can directly be used to condition an indoor space (e.g., rooms or production halls) [9].

In the desorber (generator) the water is driven off the desiccant, for example by means of an external hot water circuit. Because liquid desiccants can be regenerated at temperatures below 80°C [22], LDAC is suitable for using solar energy in combination with flat-plate solar thermal collectors as driving source. The desiccant may first be heated to raise its equilibrium vapor pressure. The desiccant is then sprayed over a bed of random fill (e.g., Raschig rings) or enters the distribution manifold to flow along microstructured plates in a plate exchanger design. Flow rates have again to be sufficient high to ensure complete wetting of the media when using filled bed design, but may be lower in a plate exchanger design in order to achieve a large concentration spread in a single step. The hot desiccant desorbs water to air that flows through the bed. Meaningfully, this air might be the return air of the air-conditioning. The moisture-laden air is typically exhausted to the ambient atmosphere. The reconcentrated rich solution functions as thermochemical storage and thus allows operation of regeneration and air-conditioning at different times.

Since the 1980s several studies on LDAC systems have been launched. In the context of these developments, the Bavarian Center of Applied Energy Research (ZAE Bayern e.V.) developed an open desiccant system aiming at a highly efficient air dehumidification in which the desiccant, 40%-concentrated LiCl/water-solution, is used not only as working fluid but also as high-capacity energy storage. In the following these developments and important thermodynamic backgrounds are explained exemplarily in brief. For more detailed descriptions, please see [22] and [23].

The main component of this development was an absorptive air dehumidifier performing a cooled absorption process to guarantee a low water vapor pressure of the desiccant and to be capable of distributing the solution flow as low as 0.2 liters per hour and m^2 (lh^{-1} m^{-2}). The higher the mass ratio between to-be-treated fresh air and aqueous desiccant solution, the higher is the concentration difference between the solution entering and leaving the absorption chamber and the higher is the achievable storage capacity. The small needed amount of desiccant solution leads to the necessary concentration difference because of its significant dilution.

The storage capacity for dehumidification enthalpy per volume diluted salt is given by Eq. 6:

$$SC = \frac{M_{air} \cdot \Delta Y \cdot \Delta h_{ev}}{V_{dil.sol}} = \Delta X \cdot \Delta h_{ev} \cdot C_{dil.sol.} \cdot \rho_{dil.sol.} \quad (6)$$

with the mass of air M_{air} [kg], the air dehumidification ΔY as the difference of the humidity ratio at the air inlet and outlet [kg/kg], the enthalpy of evaporation/condensation of pure water at T_o, Δh_{ev} [kJ/kg], the volume of the diluted solution $V_{dil.sol}$, the difference of the water content at the solution outlet and inlet of the absorption chamber ΔX, the density of the diluted solution $\rho_{dil.sol}$, and the concentration of the diluted solution $C_{dil.sol.}$.

The low solution flow and the need to spread it uniformly across the surface challenge the design of the exchanger. The air dehumidifier was designed as a flat-plate exchanger with a hydrophobic polypropylene surface to prevent corrosion. Its surface was covered by a fleece to spread the solution by capillary forces. To strengthen this effect, extra spacers between the exchanger plates caused turbulence within the through-flowing air stream.

Though a satisfactory air dehumidification and a high storage capacity could be achieved the target values were not achieved. One problem was the exchanger surface which was not managed to be wetted uniformly completely and which showed defects in its material and design. Therefore, the developments were launched with respect to alternative surfaces and solution distribution systems [22].

Recent work on advanced liquid desiccant cooling systems has been performed by various research teams in the world, for example University of Adelaide in Australia, Queens University in Canada, and Kassel University in Germany. However, only few pilot installations have been put into operation, many of them using technology from the German manufacturer Menerga or the US company AIL Research. Please see [2, 24–27, 36] for further information.

In the near future, liquid desiccant systems may play an important role in air-conditioning due to several promising advantages. LDAC is well suited for latent cooling, its electrical demand is low, and it works with low temperature–driving heat which, for example, can be supplied by low-cost solar collectors. A solar LDAC system can "operate at night" as the concentrated desiccant serves as cold storage. Also, in CHPC systems in which heat is available at a lower temperature, LDAC is worth considering [32].

Subsystems and Further Equipment Components

Besides the indicative components a solar or solar-assisted cooling system comprises further equipment components, for example the heat source and heat rejection systems. These subsystems contribute essentially to the energy performance, see the following section "Energy and Cost Performance", and for this reason are described briefly here.

The overall efficiency of a solar-assisted cooling system depends on the efficiency of each of its subcomponents and their interaction. A major component is the solar collector which yields the main part of the needed driving heat of the thermally driven cooling/air-conditioning system. Several different types of solar collectors can be used in solar cooling and air-conditioning systems. These will not be discussed here but are described in detail in the specific chapters, "▶ Solar Collectors, non-concentrating," "▶ Linear Fresnel Collectors," and "▶ Parabolic Trough Solar Technology." Further introductive and useful information is given in the section "Physical Principles" where the relation between different solar collector technologies and performance of the cooling system is discussed.

All cooling processes produce heat, for example sorption heat and heat released by the condensation process. This heat has to be rejected by heat rejection equipment. Generally, the lower the temperature of heat rejection, the lower is the needed driving temperature (see section "Physical Principles"). Lower driving temperatures lead to a higher efficiency of the solar collector and thus lead to overall lower cost per produced unit of cold. Especially for thermally driven systems, the effectiveness of the heat rejection plant is of high importance since it has a large influence on the effectiveness of the thermally driven system.

Any recooling unit needs a heat sink where the heat can be rejected. This heat sink can be either ambient air, the ground, natural water resources, or another process which is able to make use of the low-temperature heat. The majority of recooling units in practical applications make use of the ambient air; the most important technical solutions for systems using ambient air are described first and are summarized in Table 3.

Solar Cooling Systems. Table 3 Overview on common cooling towers [19]

System	Wet cooling tower	Dry cooling tower	Dry cooling tower with optional evaporative cooling	Hybrid cooling tower
Principle	Direct or indirect evaporative cooling of the refrigerant	Indirect sensible cooling by heat transfer to ambient air	Dry cooling tower with optional spraying humidification at the air side	Wet cooling tower which enables dry recooling operation in case the ambient air is at low temperature level
Water consumption	High	None	Low to medium	Medium
Advantages	High thermal efficiency, low temperatures, comparatively low electricity consumption	No problems with hygiene issues	Possible controlling of recooling temperature, reduced water consumption compared to wet cooling tower	Prevents high recooling temperature in case the ambient air is at high temperature level
Disadvantages	High maintenance requirements, high effort to avoid formation of legionellae	Comparative high electricity consumption, large construction volume	Higher complexity and maintenance compared to dry cooling towers	Higher electricity consumption compared to wet cooling towers

Wet Recooling (Open and Closed) Wet recooling includes open and closed cooling towers. The process bases on evaporative cooling, whereby in open systems the cooling water comes in direct contact with the cooling agent (air), while in closed systems the cooling water does not come in contact with the cooling agent but flows through a closed heat exchanger which is sprayed by means of a secondary circuit.

In principle, an open wet cooling tower works as follows: water exits spray manifolds, falls under the influence of gravity and takes outside air with it. While in direct contact with the air, some of the water evaporates and dissipates evaporation heat. The heat is extracted from the water stream by the air, thereby cooling it. As this design is ineffective for larger heat rejection rates, often *mechanical draft* towers are utilized which use fans or blowers to cause air to flow upward against the falling water. Towers which use an external centrifugal fan to realize the counterflow are called *forced-draft* cooling towers. The major problem in this application is that humid air can be drawn back through the cooling tower which results in a reduced performance. Another problem is the possible fan blade freezing, therefore forced draft towers are not often used under northern climate conditions. Besides forced-draft towers, there are *induced-draft* towers which use a fan to draw air through a tower fill. The back-drawing of humid air (short-circuiting) is avoided since the exit velocities are higher and the exit air plume does not mix with the air at the fan inlet. The freezing is avoided since the fan is located in the warm exit airstream. As result of the cooling tower operation, the enthalpy of the water stream decreases due to heat transfer to the cooler air and, to a minor part, due to the evaporation of water.

To design an appropriate cooling tower, the following parameters have to be considered: the heat rejection rate which is set by the condenser load of the chiller system at design cooling load conditions. The tower size (volume) increases proportionally with the load. The water-flow rate is determined by the condenser specifications and its temperature range is determined by the heat rejection rate and the tower size. The tower water outlet temperature is mostly given by recommendation of the chiller manufacturers [28].

Closed systems comprise an external and internal fluid circuit. In the external circuit, water is sprayed on tubes of a coil bundle and is exposed to the atmosphere. In the internal circuit the fluid to be cooled flows inside the tubes. Heat is transferred from the fluid flowing in the tubes to the water (drops) and to the air (by an evaporative cooling process). The air is released to the atmosphere. Compared to open cooling towers, closed ones show less efficient operation, increased electricity consumption and higher investment costs. However, some chillers require a closed recooling water loop and in such cases closed cooling towers are required. In a closed cooling tower transfer of oxygen or pollutants in the recooling cycle is avoided.

Dry Recooling (Closed) Dry air coolers transfer sensible heat to ambient air: the refrigerant to be cooled flows through a water/air heat exchanger device, but the heat exchange happens by means of convection and without evaporation. The heat is released to the ambient air.

Some dry cooling towers provide optional spraying humidification at the air side which results in cooling of the incoming air. This option can be employed for instance in cases of too high dry-bulb temperature of the ambient air for a direct operation of the recooling cycle.

Hybrid Recooling Hybrid recooling is a combination of wet and dry recooling. This provides a possible switch between latent and sensible cooling according to actual recooling power needs and temperature conditions.

Geothermal Recooling Geothermal recooling is realized by geothermal probes (vertical heat exchangers) or ground collectors (horizontal heat exchangers), whereby normally brine is used to transfer heat. In temperate climates the same system can be used as low-temperature heat source of a heat pump for heating application.

Recooling by Natural Water Resources Recooling by means of natural water resources like ground-, sea-, or river water is restricted by a limited heating permitted by law. Of course, this only works if natural water resources are geographically conveniently situated.

Recooling by a Process Which Uses Low-Temperature Heat The heat which has to be removed from the cooling system can be further used for any other process which is able to make use of low-temperature heat. An example is the heating of swimming pools or preheating of hot water, for example for showers in a swimming pool or a hotel. However, such solution depends on a suitable coincidence in terms of power and availability of waste heat from the cooling system and corresponding heating loads of the potential processes.

Further components which may be part of solar-assisted cooling/air-conditioning systems are backup devices for cold and/or heat, storage devices, several water and coolant supply subsystems, hydraulics and regulation devices, pumps, fans, filter systems, noise attenuators, and safety devices. For wider explanations please see [15, 24]. If integrated, these components also have an impact on the energy performance. For example, a buffer storage device which is added at hot water side stores surplus heat of the solar system and allows higher solar fraction. The buffer storage device can be used to support the heating or domestic water supply in phases without cooling demand. On the other hand, integration of a storage device leads to increased thermal losses. Therefore, a careful dimensioning is necessary in order to identify the best solution, that is, the solution which leads to highest energy savings compared to standard solutions. A buffer storage which is implemented at cold water side improves the operation of the cooling units. At sites with low- and high-load phases, such cold buffer storage allows continuous operation of the cold production. On the other hand, fluctuating temperatures of the cold water caused by varying solar driving energy are compensated which otherwise might lead to control problems.

An overall solar-assisted cooling/air-conditioning system is shown in Fig. 23. This scheme comprises an overall system with all possible components including a closed cycle thermally driven chiller and an open sorptive system. In reality, most systems will be composed only by parts of this comprehensive overall system.

Energy and Cost Performance

For an overall energetic and economic assessment of solar cooling/air-conditioning systems, several aspects

Solar Cooling Systems. Figure 23

Overall solar-assisted air-conditioning system with all possible components including a closed cycle thermally driven chiller and an open sorptive system

have to be taken into account: the energy saving in comparison to a conventional reference system, the first cost of the installation, and the cost difference in comparison to the conventional system. For the latter, different cost functions can be defined. However, a fair comparison has to include the complete life cycle of either system in order to provide a full picture.

Overall, there is no balance equation or value which describes a cooling system comprising all possible parameters and providing the "best" solution for a certain application "all-in-one" or "at the touch of a button." One possible approach in a design study is to begin with a sensitivity analysis based on a simulation of an annual system performance which covers an entire "performance period." Sometimes, these annual figures are called seasonal figures, for example, cooling periods do not cover a whole year but only few months (the longer the summer months of a site, the longer this cooling period lasts). The impact of the variation of important system variables on goal functions such as energy saving or life cycle costs are assessed and linked. The results can form a useful basis for further considerations and appraisals [7].

In the first part of the section "Energy and Cost Performance," the primary energy efficiency of a typical solar-assisted cooling system is investigated by performing a sensitivity analysis. In this section, also basic equations are introduced which are used to describe the energy performance of solar cooling systems. In the second part, an economic performance is taken into consideration, and results of a recent simulation study are presented.

Energy Balance

To analyze the energy balance of a solar-assisted cooling system, a scheme as shown in Fig. 24 is assumed which consists of a thermally driven chiller that receives its driving heat either from the solar collector/storage system or from the backup heat source.

The energy which is provided by the installed solar collector system and which is used for cooling purposes

Solar Cooling Systems. Figure 24
Scheme of a solar thermally driven cooling system with a fossil-fuelled backup heat source (TDC = thermally driven chiller)

is the so-called useful solar heat of a cooling system. It depends on several parameters like weather and climatic conditions, tilt angles, control concept, or failure rate during operation and construction of the solar collector. The annual solar useful heat, $Q_{sol,use}$, for a cooling application with integrated secondary heat source is given by Eq. 7:

$$Q_{sol,use} = Q_{total} - Q_{backup} \tag{7}$$

whereby Q_{total} is the total annual heat invested in the thermally driven cooling system, and Q_{backup} is the annual heat from a secondary heat source, also called backup heat source.

The solar fraction SF_{cool} is the amount of heat requirements for cooling that can be met by a solar energy source, see Eq. 8:

$$SF_{cool} = 1 - \frac{Q_{backup}}{Q_{total}}. \tag{8}$$

The solar fraction thus ranges from zero for no solar energy utilization to 1 for all energy provided by solar.

Saving (fossil) primary energy is the main reason for the application of solar or solar-assisted cooling systems.

The total primary energy consumed by a solar-driven system PE_{sol} is the sum of the primary energy demand of all fossil-fuelled sources of the system PE_{fuel} and the primary energy demand of all components that consume electricity PE_{el}, see Eq. 9:

$$PE_{sol} = PE_{fuel} + PE_{el} = \frac{E_{fuel}}{\eta_{PE,fuel}} + \frac{E_{el}}{\eta_{el,grid}}. \tag{9}$$

E_{fuel} is the secondary energy provided by fuel. $\eta_{PE,fuel}$ describes the primary energy efficiency of the fuel used to operate the backup heat source. As example, for natural gas the primary energy factor is less than 1 because of grid losses and the embodied primary energy for keeping the pressure of the natural gas network. E_{el} is the electricity needed to operate the system, for example, the electricity needed to operate circulation pumps, the recooling system and the system control. $\eta_{el,grid}$ is the efficiency of the electric network system which depends on the structure of the electricity production and network of each country (for instance, for the EU, the average value of $\eta_{el,grid}$ is about 40%).

When looking at the system energy performance in detail, all the auxiliary energy consumers such as pumps, fans, control units, etc., have to be taken into consideration. The main subsystems which consume primary energy are the backup heat system (e.g., gas boiler), the solar subsystem, the thermally driven chiller itself and the heat rejection subsystem. Electricity is mainly consumed for the collector cycle, the thermally driven cooling machine itself (e.g., refrigerant pump, control unit) and the heat rejection device (cooling tower, cooling cycle pump). The corresponding equations of these subsystems are introduced in the following.

The primary energy demand of the fossil-fuelled backup heat source is given by Eq. 10:

$$PE_{backup} = \frac{Q_{cold}}{COP_{annual}} \cdot \frac{1 - SF_{cool}}{\eta_{backup} \cdot \eta_{PE,fuel}} \tag{10}$$

where COP_{annual} describes the average thermal COP of the system considered over a 1-year period, and η_{backup} is the energy efficiency of the backup heat system.

The primary energy of the electricity consumption of the solar collector subsystem, mainly pumps, is given by Eq. 11:

$$PE_{coll} = \frac{Q_{cold}}{COP_{annual}} \cdot \frac{SF_{cool} \cdot f_{el,sol}}{\eta_{PE,grid}}, \tag{11}$$

with the electric efficiency factor of solar heat generation

$$f_{el,sol} = \frac{E_{el,sol}}{Q_{sol}}. \tag{12}$$

$E_{el,sol}$ is the annual electricity consumption to operate the solar system and Q_{sol} denotes the annual useful solar gains for cooling.

The primary energy consumption of the thermally driven chiller includes also the electricity to operate the pump of the driving heat cycle and is defined by Eq. 13:

$$PE_{TDC} = \frac{Q_{cold} \cdot f_{el,TDC}}{\eta_{PE,grid}}, \tag{13}$$

with the electric efficiency factor for the thermally driven chiller

$$f_{el,TDC} = \frac{E_{el,TDC}}{Q_{cold}}. \tag{14}$$

$E_{el,TDC}$ is the annual electricity consumption to operate the thermally driven chiller (for instance, the solution and refrigerant pump in an absorption chiller).

The primary energy consumption of the heat rejection subsystem, including the cooling cycle pump, is given by Eq. 15:

$$PE_{reject} = \frac{Q_{cold}}{COP_{annual}} \cdot \frac{f_{el,reject} \cdot \left(1 + \frac{1}{COP_{annual}}\right)}{\eta_{PE,grid}}, \tag{15}$$

with the annual electric efficiency factor for the heat rejection device

$$f_{el,reject} = \frac{E_{el,reject}}{Q_{reject}}. \tag{16}$$

$E_{el,reject}$ is the annual electricity consumption to operate the heat rejection device and Q_{reject} is the annual rejected heat given by the sum of the driving heat of the thermally driven chiller, Q_{heat}, and the produced cold, Q_{cold}, see Eq. 17:

$$Q_{reject} = Q_{heat} + Q_{cold} = Q_{heat} \cdot (1 + COP_{annual}) \tag{17}$$

The summation of the equations for the different subsystems leads to a formula for PE_{sol}, see Eq. 18:

$$PE_{sol} = \frac{Q_{cold}}{COP_{annual}} \cdot \left(\frac{1 - SF_{cool}}{\eta_{backup} \cdot \eta_{PE,fuel}} + \frac{SF_{cool} \cdot f_{el,sol}}{\eta_{PE,grid}} + \frac{COP_{annual} \cdot f_{el,TDC}}{\eta_{PE,grid}} + \frac{f_{el,reject} \cdot (1 + COP_{annual})}{\eta_{PE,grid}} \right) \tag{18}$$

Implementation of a solar or solar-assisted cooling installation only makes sense if there is a considerable lowering of primary energy consumption compared to a conventional system. To this aim, it is suitable to calculate both a conventional system which is able to accomplish the same task as the solar cooling system but with no use of solar energy [13] and a solar system of which the primary energy savings and cost for saved primary energy shall be determined.

The efficiency of a conventional system, for example an electric chiller based on vapor compression, is described with the Energy Efficiency Ratio EER, defined as the useful cold Q_{cold} per supply energy W (in most cases, W is in form of electricity, and the chiller is composed of both the compressor cycle and the electric motor to run the compressor), see Eq. 19:

$$EER = \frac{Q_{cold}}{W} \tag{19}$$

The primary energy consumption of the reference system, PE_{ref}, which is completely based on electricity operation, is given by Eq. 20:

$$PE_{ref} = \frac{Q_{cold}}{EER_{annual} \cdot \eta_{el,grid}} \tag{20}$$

with EER_{annual} describing the average EER of the conventional driven chiller of an overall considered cooling period.

The annual primary energy savings PE_{sav} are given by:

$$PE_{sav} = PE_{ref} - PE_{sol} \tag{21}$$

and the fractional primary energy savings are defined as:

$$f_{PE,sav} = 1 - \frac{PE_{sol}}{PE_{ref}} = \frac{PE_{sav}}{PE_{ref}} \tag{22}$$

In the following, the above defined equations are used to derive some basic insights in the primary energy performance of solar thermally driven cooling systems. For this purpose, a sensitivity analysis is carried out for which a set of standard parameters is used, see the values given in Table 4.

The main results which are provided by such an analysis are displayed graphically, see Figs. 25, 26 and 27.

As Fig. 25 shows, the solar fraction for cooling has a strong influence on the fractional primary energy

Solar Cooling Systems. Table 4 Set of standard values for the various parameters in a sensitivity analysis

Parameter	Meaning	Standard value
$\eta_{PE,fuel}$	Primary energy efficiency of the fuel at application site	0.95
η_{backup}	Energy efficiency of backup heat source	0.9
SF_{cool}	Solar fraction for cooling (i.e., for driving heat of the TDC)	0.9
$\eta_{PE,grid}$	Primary energy efficiency of electric grid	0.4
EER_{annual}	Annual efficiency of the reference cooling system, here: air-cooled compression chiller	3.0
COP_{annual}	Annual thermal COP of the thermally driven chiller	0.7
$f_{el,sol}$	Electric efficiency factor of the solar subsystem, kWh_{el}/kWh_{th}	0.02
$f_{el,TDC}$	Electric efficiency factor of the TDC subsystem, kWh_{el}/kWh_{cold}	0.02
$f_{el,reject}$	Electric efficiency factor of the heat rejection subsystem, kWh_{el}/kWh_{reject}	0.03

Solar Cooling Systems. Figure 25
Fractional primary energy savings as a function of the solar fraction for cooling for different values of the COP of the thermally driven chiller

savings of solar cooling systems. Positive values on the y-axis indicate a positive fractional primary energy saving and thus a lower primary energy consumption of the solar-driven system when compared to a reference solution. In particular, for systems with a low seasonal COP of the thermally driven chiller, the effect is significant and a too low solar fraction can even lead to higher primary energy consumption than for the conventional reference, negative values of the $f_{PE,sav}$. The reason is that a significant amount of cooling is produced by converting primary energy of a fossil fuel into cold with a low COP of the thermally driven cooling device and thus with a low overall conversion rate. Figure 25 also shows that an operation of the thermally driven cooling system which is completely driven by solar energy, that means SF_{cool} = 1, leads to significant primary energy savings. This corresponds either to a system where cooling is only provided if sufficient solar energy (or energy from a solar-driven heat buffer) is available or to a system

Solar Cooling Systems. Figure 26
Fractional primary energy savings as a function of the electric efficiency factor of the heat rejection subsystem for different values of the COP of the thermally driven chiller

Solar Cooling Systems. Figure 27
Fractional primary energy savings as a function of the COP of the reference chiller for different values of the COP of the thermally driven chiller

with a conventional backup compression chiller that provides cooling in case of absence of solar thermally driven cooling. However, such system requires that an electrically driven compression system is installed beside the thermally driven cooling device.

Another important influence is due to the efficiency of the heat rejection system, as can be seen from Fig. 26. The amount of electricity needed for heat rejection depends strongly on the heat rejection technology which is used. The amount of electricity for heat rejection can be kept low by using highly efficient components, for example highly efficient pumps and fans, and by employing speed-controlled components which can be operated at reduced capacity under part-load conditions.

Finally, the fractional primary energy savings of course depend on the EER of the conventional reference system. Values of decentralized small room

air-conditioners typically range from 2 to 2.5. Values of large centralized compression water chillers using wet cooling towers can be up to 5. The influence of this parameter and the fractional primary energy savings are depicted in Fig. 27.

Economical Assessment

One of the most important and interesting questions is the one of the cost effectiveness of any optional system. A cost calculation bases on the annual energy balance of a solar system, see section "Energy Balance." The calculation has to complete the balancing of the whole system with an economical consideration and aims especially at the cost of saved primary energy. As in the case of the primary energy balancing, this cost calculation is performed for both a solar system and a conventional reference system which covers the same loads. Obtained results are compared to each other.

The cost of saved primary energy $C_{PE,sav}$ is defined by Eq. 23:

$$C_{PE,sav} = \frac{C_{annual,sol} - C_{annual,ref}}{PE_{sav}}. \tag{23}$$

$C_{annual,\ sol}$ corresponds to the sum of all annual costs of the solar system; $C_{annual,\ ref}$ relates to the sum of all annual costs of the conventional reference system. A negative value of $C_{PE,sav}$ means that the system amortizes within its lifetime, at least as long as PE_{sav} is positive, that is, the solar-driven system consumes less primary energy as the conventional reference. The $C_{PE,sav}$ turns out as a very useful figure of merit as it combines energy and cost performance and allows comparison of different systems on the basis of a single parameter. But it makes only sense as long as the total annual cost of an alternative solution leads to higher total annual cost than the conventional reference. Only in such case the relation between expenditure – higher annual cost – can be related to a benefit – saving of primary energy. Then minimizing of $C_{PE,sav}$ can contribute to make a decision between different possible solutions.

In case the solar solution leads to lower total annual cost and saves primary energy, a goal function, F, which combines economic- and energy-related parameters has to be introduced. A possible, of course arbitrary, goal function would be the sum of the fractional cost saving $f_{cost,sav}$, defined as

$$f_{\cos t,sav} = \frac{C_{annual,ref} - C_{annual,sol}}{C_{annual,ref}} \tag{24}$$

and the fractional primary energy saving $f_{PE,sav}$, called F_1:

$$F_1 = \frac{C_{annual,ref} - C_{annual,sol}}{C_{annual,ref}} + \frac{PE_{annual,ref} - PE_{annual,sol}}{PE_{annual,ref}} = f_{cost,sav} + f_{PE,sav} \tag{25}$$

Another way to describe more distinctly the difference between several solutions is achieved by replacing the summation of Eq. 25 through a multiplication of the fractional cost saving and fractional primary energy saving. This goal function F_2 is defined as:

$$F_2 = \frac{C_{annual,ref} - C_{annual,sol}}{C_{annual,ref}} * \frac{PE_{annual,ref} - PE_{annual,sol}}{PE_{annual,ref}} = f_{\cos t,sav} * f_{PE,sav} \tag{26}$$

Although, at first sight, Eqs. 23, 24, 25 and 26 seem to be simple, they are based on a complex interaction of many different aspects. All costs of a system's design, construction and operation phase for the whole life cycle have to be involved and put in an annualized way. This includes, for example, the total investment costs, financing costs, costs of the energy consumption of supporting systems like pumps or cooling towers, and other costs such as for maintenance. For the energy and cost calculation, also a total annual energy balance has to be made including cooling, heating and hot water production (depending on all purposes and functions of the specific system) since the solar collector field can be used for all these applications.

Due to its complexity, the calculation of the annual energy balance is usually done by a computational simulation program, for example TRNSYS [47]. The different programs may differ but operate on similar principles. To get an idea of the considerations and conditions which are behind such a simulation program, a short overview of its sequences is given below. The applied methodology was developed within the SACE project. To gain a more detailed insight, [15] and [44] are recommended.

At the very beginning of the calculation, two site-specific time series are generated with each series covering a period of a year; typically, hourly average values for all variables are used.

The first time series includes the hourly values of total irradiation on the solar collector of the solar system which is under consideration and ambient air temperatures. These values influence the solar gains of a certain system with specific conditions. They can, for instance, be obtained by the national weather services.

The second time series displays the cooling and heating demand of the building which loads have to be covered and are the same for solar and reference system. Such time series can be computed by use of dynamic (multizone) building simulation.

These data series form the application-specific basis of the calculation performance and have to be created for each individual project. Combined with the balance equations introduced in section "Energy Balance," the simulation program generates the corresponding results. Table 5 shows an energy analysis spreadsheet and Table 6 an economic assessment spreadsheet. Both are commonly used approaches to display the results of a cost calculation and to determine the cost of saved primary energy.

The section "General Data" contains data of the dimensions of the system components such as the solar collector, the buffer tank, the chiller, and the air-handling unit. These values have to be inserted by the user for both the reference system and the solar system.

Solar Cooling Systems. Table 5 Energy analysis spreadsheet to compare a solar thermal system with a reference system (example values from a simulation study; for more details see [15])

Energy analysis spreadsheet	Unit	Reference system (R)	Solar system (S)
0. General data			
Solar collector type	–	–	–
Solar collector area (aperture)	m^2

Cost of saved primary energy	**€/kWh**	**–**	**0.005**

The section "Results of System Design" contains the main results of an annual energy balance which can be derived using a simulation program, a design tool, or any other calculation method. To allow comparison of the solar system performance with a reference system, comparable figures of a reference system have to be entered.

The "energy-related evaluation" provides energy-related performance figures which are calculated based on the annual simulation results from section "Definition of the Subject and Its Importance" of the work sheet, that is, results of system design. The following figures are not self-explaining and thus described.

The annual gross collector efficiency, η_{gross}, is defined by Eq. 27:

$$\eta_{gross} = \frac{Q_{coll}}{A_{coll} \cdot I_{coll}} \tag{27}$$

where Q_{coll} is the annual heat production of the solar system including unused excess heat, A_{coll} is the solar collector's aperture area, and I_{coll} is the annual

global (total) solar radiation incident on the solar collector plane.

The net collector efficiency, η_{net}, is defined by Eq. 28:

$$\eta_{net} = \frac{Q_{use}}{A_{coll} \cdot I_{coll}} \tag{28}$$

The net collector efficiency can be compared to the annual gross collector efficiency. The difference indicates the amount of solar energy that cannot be used because there is no actual demand for the available solar energy, and the available heat buffer is fully charged.

In the following, items of the economic assessment spreadsheet which are not self-explanatory are briefly described.

The total annual cost, C_{annual}, of a system is composed of the investment and maintenance and operation costs, see Eq. 29. The respective costs are explained later in this chapter.

$$C_{annual} = C_{investment,annual} + C_{maintenance,annual} + C_{operation,annual} \tag{29}$$

Firstly, the initial investment costs have to be carefully calculated. Main cost items to be considered are given in the list below:
Direct on-site costs are:

- Purchased equipment cost, which is dominated by costs for the chiller system and the solar collector. For both components, the specific cost (cost per unit) decreases with the installed size (typically expressed kW of cooling capacity for chillers and m^2 of aperture area for the solar collector field).
- Purchased equipment installation
- Piping
- Instrumentation and controls
- Electrical equipments and materials

Direct off-site costs are caused by:

- Land
- Civil, structural, and architectural costs
- Service facilities

Indirect costs include:

- Engineering and supervision
- Contractor's profits
- Contingency

Other depending costs are:

- Start-up costs
- Licensing, research and development
- Allowances for funds used during construction [5]

To calculate the investment cost, an annual basis accounting for the value of money over time has to be taken into consideration. This can, for instance, be made by spreading the initial investment, C_{inv}, over the lifetime of the system in years in constant annual quantities, called annuities, according to Eq. 30:

$$C_{investment,annual} = C_{inv} \cdot \frac{i_{eff}}{1 - (1 + i_{eff})^{-n}} \tag{30}$$

Here, i_{eff} is the effective rate of return, which can be estimated as the difference between the average interest rate offered by the banks and the inflation rate and n denotes the considered lifetime period.

Operating costs are due to fuel, electricity, wages, supplies and water. Maintenance costs are due to maintenance parts and services. Energy consumption is an important part of operating cost and the amount of consumed energy depends on the efficiency of the system. Electricity rates are usually more complex than those of gas or water. For instance, the price may be different according to the season and the time of the day, or can increase when a consumption threshold is overcome [3].

Once the annual maintenance costs, $C_{maintenance,annual}$, and the annual operating costs, $C_{operation,annual}$, have been calculated, combination of Eqs. 29 and 30 allows calculation of the total annual cost of either system. Together with the calculated annual amount of saved primary energy, PE_{sav}, this allows calculation of the cost of saved primary energy according to Eq. 23.

In the following, results of a simulation study are presented in which different systems were compared including solutions using photovoltaic installations.

Methodology of Economical Assessment – An Exemplary Simulation Study

The goal of the study presented below is to assess the energy saving potential and related economic results of different solar energy solutions for a given load. As an example, a (virtual) hotel in Madrid was chosen. The study is based on dynamic building simulation to

produce a load file and includes subsequent modeling of different solar-assisted systems to cover this load. The load is characterized by hourly values for heating load, cooling load, heat demand for preparation of sanitary hot water SHW (e.g., for showers) and electricity demand for artificial lighting and appliances.

Different systems were simulated to cover this load:

- A conventional reference system consisting of a natural gas-fuelled condensation boiler to cover the energy demand for heating and SHW and a vapor compression chiller to cover cooling. Electricity demand is completely covered by the public grid.
- A system using a solar thermal collector to partly cover the heating and SHW demand and a natural gas-fuelled condensation boiler to cover the rest of heating and SHW. A vapor compression chiller is used to cover the cooling demand. The electricity demand is completely covered by the public grid.
- A system using a solar thermal collector to partly cover the heating and SHW demand and to operate a thermally driven chiller which covers part of the cooling demand. A natural gas-fuelled condensation boiler is used to cover the rest of the energy demand for heating and SHW and a vapor compression chiller to cover the rest of the cooling demand. Electricity demand is completely covered by the public grid.
- A system consisting of a natural gas-fuelled condensation boiler to cover the energy demand for heating and SHW and a vapor compression chiller to cover the cooling demand. In addition, a photovoltaic (PV) system is used to cover part of the electricity demand. Electricity demand which is not covered by the PV is covered by the public grid. PV electricity which exceeds the actual electricity demand is fed into the public grid.

The general approach of the study is shown in Fig. 28, and schematics of the four different system configurations are shown in Fig. 29.

The assumed hotel has a total floor area of 3,050 m^2, and the building was divided in four different zones for generation of the load file (guest rooms, restaurant, kitchen, lobby, and others) using dynamic multizone building simulation. The annual values for the energy demand add up to 166 MWh for electricity (54.4 kWh/m^2a), 164 MWh for heating (53.6 kWh/m^2a), 78 MWh for cooling (25.4 kWh/m^2a), and 155 MWh for sanitary hot water (51.0 kWh/m^2a).

The key components used in the simulation are the following:

- Advanced flat-plate collector tilted 30° toward south with different sizes (100, 200, 500 m^2)
- Heat buffer storage with a size of 55 l m^{-2} of solar collector aperture area

Solar Cooling Systems. Figure 28
Methodology of the simulation study

Solar Cooling Systems. Figure 29
Schematics of four compared system configurations: conventional reference (*top left*), solar thermal heating (*top right*), solar thermal heating and cooling (*bottom left*), and PV system (*bottom right*)

- Thermally driven chiller with average thermal COP of 0.68 with different sizes (10-kW, 20-kW, 40-kW cooling capacity)
- Cooling tower with a nominal electric efficiency factor of the heat rejection subsystem of 0.04 (i.e., 1 kWh of consumed electricity per 25 kWh of rejected heat)
- Vapor compression chiller with an average EER of 3.0
- Natural gas condensation boiler with an average efficiency of 0.9
- PV system: PV system using monocrystalline Si wafer PV modules tilted 30° toward south with different sizes (8, 80 kW_{peak})

Regarding costs, the following assumptions were used:

- For all components with a strong dependence of the first cost on the size cost curves have been used (see Fig. 30). These values do not include planning and installation.
- For the PV system, a fix price of 3 € per W_{peak} was assumed. This value includes planning and installation cost.
- No subsidies or incentive schemes for any of the technologies were used in order to generate a fair picture about the real cost of the different technologies.
- The rate of reimbursement for electricity produced by the PV system which exceeds the actual demand and which is fed into grid amounts 50% of the tariff for which electricity is purchased.
- Other important parameters used in the simulation such as energy prices, system lifetime, interest rate, primary energy conversion rates, etc., are summarized in Table 7.

As a first result, Fig. 31 presents the solar fraction achieved with the various solar thermal solutions. Five different variants are shown: two system configurations where solar thermal energy was used for heating and SHW only, and three configurations where a thermally driven chiller was installed additionally. The smallest solar thermal system considered (collector aperture area, A_{coll}, 100 m^2) covers about 40% of the SHW demand and a little less than 20% of the heating demand. Doubling the collector area leads not to a doubling of the useful output of the solar thermal system. Reason is that, in many hours, solar gains exist, but no actual load is available and the heat buffer is fully charged. This happens particularly in summer and in transition periods (fall, spring) when no demand for heating exists. Some use of this surplus heat can be made by adding a thermally driven chiller to the system. About 20% of the cooling demand can be covered by the solar thermal cooling system if, for instance,

	PE factor fuel $f_{PE,fuel}$	kWh_{PE}/kWh_{fuel}	1.1

a chiller with a maximum cooling capacity of 20 kW is used. However, this leads only to a small increase when looking at the total thermal energy demand for heating, cooling, and SHW. A significant contribution to the cooling demand (close to 60%) is achieved by the solar thermal system with a much larger solar collector field (500 m^2) and a thermally driven chiller with a cooling capacity of 40 kW. Such configuration allows almost 70% of the total thermal energy demand to be covered by solar energy.

A comparison of solar-assisted systems and the conventional reference can be expressed by both primary energy saving and cost difference. Figure 32 shows the fractional primary energy saving (according to Eq. 22 in section "Energy Balance") and the fractional cost saving (according to Eq. 24 in section "Energy Balance") for different system configurations.

All investigated systems lead to primary energy savings. Figure 32 also indicates that a comparatively small solar thermal system (100, 200 m^2) for heating and sanitary hot water leads to cost saving. The system amortizes within its lifetime under the conditions made. The cost saving is less pronounced when the solar thermal system is also for cooling. Large solar thermal systems (500 m^2) lead to higher total annual cost compared to the conventional solution or – in other words – such system does not amortize within its assumed lifetime. Installation of a small- to medium-sized photovoltaic system (8–40 kW_{peak}) in addition to the conventional system leads to a negligible difference in total annual cost. A large PV system (80 kW_{peak}), however, leads to an increase in total annual cost. Reason is that, at many times, electricity is produced which cannot be consumed onsite and is therefore fed into the grid at a feed-in tariff which amounts 50% of the rate for purchased electricity.

In addition to the systems described previously, Fig. 32 also shows a configuration with a small solar thermal system (100 m^2) and a small PV system (8 kW_{peak}) being installed together. It is interesting to note that this solution leads to the highest decrease in total annual cost and it has the shortest payback period.

For a combined energy-cost-performance assessment, the goal functions defined in section "Energy Balance" may be applied. In Fig. 33, the goal functions F_1 and F_2 are presented for those solutions which lead to a lower total annual cost in comparison to the conventional reference system. Both definitions of goal functions lead to the same result about the three best solutions of the studied configurations: these are a solar thermal system used for heating and sanitary hot water with 200 m^2 of collector area, followed by the combined solar thermal (100 m^2) and small PV system (8 kW_{peak}), and then the solar thermal system with 200 m^2 of collector area with an additional small thermally driven chiller (10-kW cooling capacity). The results shown in Fig. 33 confirm that the second goal function F_2 leads to a more pronounced difference between the different solutions.

The results shown for the example of the hotel in Madrid are specific for the given boundary conditions, particularly meaning climatic conditions which influence both solar gains and load demand. The load conditions are typical for a hotel but will vary significantly in case of other buildings and purposes. Nevertheless, some general conclusions can be drawn which are valid for the system design of building energy supply and, in particular, for the use of solar energy systems in buildings.

Solar fraction for heating, sanitary hot water (SHW), cooling, and total thermal energy demand for different solar thermal system configurations (A_{coll} collector aperture area; PTDC: nominal cooling capacity of the thermally driven chiller)

Solar Cooling Systems. Figure 32
Fractional primary energy saving and fractional cost saving for different solar-assisted solutions in comparison to a conventional reference system

- Solar thermal systems will be justified in most cases where a high demand of sanitary hot water exists. These systems are most cost-efficient if they are sized in such way that no significant excess heat is produced by the solar collectors and the solar fraction is not maximized.
- Solar thermally driven cooling is an interesting option in order to make use of high solar gains during the

Solar Cooling Systems. Figure 33
Comparison of different system configurations using the combined energy-cost-performance goal functions F_1 (Eq. 25) and F_2 (Eq. 26) (y-axis arbitrary units)

cooling period. The system will be more cost-efficient if it is designed with limited solar fractions. However, this solution is still less cost-efficient in comparison to solar thermal systems without cooling. Future improvements will lead to cost reductions such as higher production rates – and corresponding lower cost – of thermally driven cooling devices and more standardized system designs which will lead to lower planning and installation costs.

- Today, photovoltaic systems rely on high feed-in tariffs in many countries and on an almost infinite grid capacity in comparison to the electricity production by solar energy. Therefore, if the high feed-in tariff is taken into account today, any PV solution will be much more interesting from a cost point of view than most solar thermal systems. However, with increasing production of electricity from renewable sources, this situation will change drastically in the future. Grid issues will become much more important and, among others, the pressure on locally produced electricity (e.g., from PV) will increase to be consumed onsite, too.
- In particular, for solar thermal systems – but in future also for PV systems – a detailed assessment of the correlation between solar gains and onsite loads is important. This analysis can usually only be done appropriately by a simulation of both the load side and the production systems on a sufficiently low time scale. Typically, simulations based on hourly values provide a not only helpful but also reliable basis for a detailed analysis.
- A holistic approach which includes an analysis of different combinations and configurations of technologies is needed in order to identify the optimal solution for a given project with its particular boundary conditions. Combined energy-cost-performance analysis and corresponding goal functions can provide a guide to these optimal solutions.

The large amount and diversity of results and newly gained know-how affirms the fact that performance and operation of (solar or solar-assisted) cooling systems depend on many aspects which are not completely fathomed. Therefore, further research and development actions are needed. One of the most important parts of running research projects are demonstration projects to gain practical insight. Some examples of practical projects are depicted in section "System Experiences."

System Experiences

The first part of section "System Experiences" points out some examples of the existing systems. Examples of

absorption or adsorption cooling as well as examples of solid and liquid desiccative air-conditioning are displayed. Relevant facts like size of the installations, climate zones, and the type of the utilized solar collectors are mentioned. In the second part, experiences which have been made with these installations are discussed.

Examples of Existing Installations: Closed Absorption Systems, Single-Effect

See Table 8.

Examples of Existing Installations: Closed Absorption Systems, Double-Effect

Summary of Experiences

The experiences obtained in demonstration projects and by monitoring of solar cooling plants lead to a valuable collection of know-how in the field of solar and solar-assisted cooling systems.

A major result of the R&D and demonstration work so far is that solar and solar-assisted cooling and air-conditioning systems can lead to significant primary energy savings. That and the fact that the interest of planners, building facility managements, solar companies – and the public in general – in solar thermal air-conditioning increases could give the necessary drive and the still indispensable support to make such systems an unconditional alternative. To sum up some important collected experiences following technical aspects might help to take the right steps into the right directions.

The design phase as well as the commissioning and operation phases has to be carried out accurately and under strict quality criteria.

A software tool is more than useful to design a solar cooling system. There is a need for careful design with particular focus on minimizing parasitic electric demand. Design and simulation studies support the selection and sizing of the appropriate components and determine the potential savings in primary energy. Experiences from monitored systems reveal optimization potential in system control and hydraulic schemes, as the designed systems are often too complex and the system performance was often not able to fulfill the expectations (relevant for Solar Cooling are the projects SACE, ASODECO, MITES, ROCCOCO, SOLAIR, SOLERA, MEDISCO, HIGHCOMBI, SOLARCOMBIPLUS). The planning and installation of large solar collector areas require special attention with respect to well-balanced mass flow and stagnation safety. Size and type of the solar collector and storage volume depends strongly on the site conditions, load structure and applied air-conditioning technology.

The choice of market introduction is quite deliberate, too. Best niches for market introduction are places with high electricity cost and limited quality and security of electricity supply, for example hotels on islands.

Main challenges are that in most cases solar-assisted cooling is not yet economically competitive under present market conditions without funding measures. And even if cost-competitive over the complete life cycle their operation will not lead to a short return-on-invest period. Also, well-trained installation and operation staff is needed in order to assure high quality.

The prepared solar cooling concepts have to be evaluated reasonably with respect to savings in primary energy and greenhouse gas emissions. For thermally-operated cooling processes with low COP and use of fossil fuels (backup heat), a high percentage of solar thermal coverage is required in order to achieve savings in primary energy and CO_2 emissions. Alternatively, an electrically driven compression chiller may be installed as backup solution for the cooling case. In general, further efforts to increase the thermal COP of thermally driven chillers and electric performance of the entire systems are required to exploit the existing saving potential.

Another finding is that improvements in the building shell are prerequisite to reduce the cooling loads for

the installation of a solar thermal air-conditioning system. The load (and climatic) conditions mainly effect the ROI, namely the number of operation hours, and cost of conventional energy sources. In general, the implementation of storages – either on the hot side or on the cold side – is essential to handle time shifts between solar thermal heat generation profile and load profile. A high correlation between solar gains and cooling loads occurs mainly in buildings with dominating external loads and usage during day hours.

A promising direction are new developments of small chillers (<15-kW capacity) for residential and commercial use as these systems open new market sectors, especially in southern European areas.

Although the reliability of such system operations and environmental savings exist, there is still a large potential for further improvements in terms of efficiency, compactness of the systems and cost. Production capacities of the involved manufacturers are still low and increased volume of production rates would allow highly increased automation. To decrease the investment costs, it is also necessary to create more standardized system solutions for small (and medium size) applications.

For any economical working application, the exploitation of the solar thermal system should be maximized using the system for space heating support and – if needed – production of SHW. The combination of heating support, domestic hot water preparation and solar cooling optimizes the use of the solar thermal system throughout the year and improves the cost effectiveness.

Besides small chillers and SHW different concepts to extend existing HVAC plants to solar assistance at large scale level is a point of interest of commercial applicants.

Future Directions

Several thermally driven air-conditioning technologies are available on the market and enable the use of solar thermal energy for this large field of possible applications. Solar or solar-assisted air-conditioning can lead to remarkable primary energy savings if the corresponding systems are properly designed. Aspects are an appropriate dimensioning of the size of the collector field and the storage devices as well as heat and cold backup source.

In the last years, several efforts have been made in order to develop new thermally driven cooling equipment. Two main directions have been the development of thermally driven water chillers in the range of low cooling capacities (<50 kW down to less than 5 kW) and the further development of advanced open cycles. Different technologies are employed for the purpose of low-capacity water chillers with concepts using liquid sorption materials such as LiBr or NH_3 as well as solid ones such as silica gel and zeolite or solid absorption using salt/water systems. Several R&D activities have focused on the development of open cooling cycles using liquid desiccants. Liquid desiccants have some important advantages compared to systems using sorption wheels as described above. With liquid desiccants, it is possible to separate the processes of absorption and regeneration in time and thereby to use the liquid sorption material as thermochemical storage. The precondition to achieve high storage densities is to establish a highly efficient absorption process which leads to a large difference between concentration of concentrated and diluted solution. Another advantage of using liquid desiccants is that it is easier to cool the sorption process and thereby to realize a higher dehumidification with low regeneration temperatures compared to the usual desiccant cooling system. One of the recent R&D projects also deals with an advanced solid sorption process in which the sorption process is cooled in order to obtain a large dehumidification of

the process air. Improvements in the performance of thermally driven chillers and open cooling cycles play a key role in order to approach economic feasibility. New developments of chillers with small capacity will open new market segments. For hot climates, high temperature lifts, that is, temperature differences between temperature of the produced cooling and the heat rejection are necessary. Under these conditions, high-efficiency solar collector systems which are tracking the sun in combination with efficient single-effect systems are a promising future option. Also in this area, a number of promising pilot installations have been realized and opened a broader market deployment, in particular in sunny regions like the Mediterranean countries [14].

Numerous simulation and demonstration projects, many of them supported by the European Commission (relevant for Solar Cooling are the projects SACE, ASODECO, MITES, ROCCOCO, SOLAIR, SOLERA, MEDISCO, HIGHCOMBI, SOLARCOMBIPLUS),

made it possible to provide a lot of useful information and develop strategies concerning further steps and future directions. Recently, many demonstration projects have been realized within the framework of the Solar Heating & Cooling Programme of the International Energy Agency IEA. TASK 25 "Solar Assisted Air-Conditioning of Buildings" (1999–2005) and TASK 38 "Solar Air-Conditioning and Refrigeration" (2006–2010) were large international activities with participation of research institutes, universities, and commercial partners (manufacturers, installation companies, planning offices) which contributed to technology development of solar cooling and provided accompanying measures for a faster and solid market development. For further information, see [50].

Future research has to focus on all levels starting from material research, in particular in the field of advanced sorption materials through process design and system optimization, up to the provision of accompanying measures for a broader and sustainable market introduction. All the concepts and technologies which were described in this chapter will contribute to the use of solar energy for air-conditioning of buildings and refrigeration. Well-adjusted solutions for the various boundary conditions, different climatic situations and different load conditions will be developed. Always an integrated approach is needed in which all the energy flows within a process or building are taken into consideration in a holistic approach in order to identify the best suited solar energy solution.

Glossary

Absorber tube The tube through which the fluid is to be illuminated and/or heated up in a solar collector.

CPC Compound parabolic collector. They are static collectors with a reflective surface following an involute around a cylindrical reactor and have been found to provide the best optics for low-concentration systems.

Electron/hole Negative and positive charge generated in an illuminated semiconductor. The excited electrons are transferred to the reducible specimen at the same time that the catalyst accepts electrons from the oxidizable specimen, which occupies the holes. In both directions, the net flow of electrons is null and the catalyst remains unaltered.

Immobilized catalyst Anchoring the catalyst onto some type of inert support inside the reactor.

Mineralization Conversion of organic compounds to inorganic ones. These inorganic compounds are

usually carbon dioxide, water, and acids (nontoxic substances).

Photocatalysis Combination of photochemistry with catalysis. Both light and catalyst are necessary to achieve or to accelerate a chemical reaction. Photocatalysis may be defined as the "acceleration of a photoreaction by the presence of a catalyst." Heterogeneous processes employ semiconductor slurries for catalysis, whereas homogeneous photocatalysis is used in a single-phase system.

Photo-Fenton Combination of Fe^{2+}, H_2O_2, and irradiation for producing hydroxyl radicals. The main advantage of the photo-Fenton process is the light sensitivity up to a wavelength of 550 nm.

Photoreactor Reactor where a photochemical reaction takes place.

Quantum yield The ratio between the number of reacting molecules of target compound or product formed and the quantity of photons absorbed by the system.

Semiconductor Material with an appropriate energetic separation between its valence and conduction bands which can be surpassed applying external energy (e.g., light). Metal oxides and sulfides represent a large class of semiconductor materials suitable for photocatalytic purposes.

Solar photochemistry This term includes those chemical processes which use the sun to drive specific chemical reactions by direct absorption of solar photons.

Definition of the Subject and Its Importance

One of the most pervasive problems affecting people throughout the world is inadequate access to clean water and sanitation. Problems with water are expected to grow worse in the coming decades, with water scarcity occurring globally, even in regions currently considered water rich. Addressing these problems calls out for a tremendous amount of research to be conducted to identify robust new methods of purifying water at lower cost and with less energy while at the same time minimizing the use of chemicals and impact on the environment. More effective, lower-cost, robust methods to disinfect and decontaminate waters from source to point-of-use are needed, without further stressing the environment or endangering human health by the treatment itself.

Advanced oxidation processes (AOPs) may be used for decontamination of water containing organic pollutants, classified as biorecalcitrant, and/or for disinfection removing current and emerging pathogens. These methods rely on the formation of highly reactive chemical species which degrade even the most recalcitrant molecules into biodegradable compounds. Although there are different reacting systems, all of them are characterized by the same chemical feature: production of hydroxyl radicals (•OH), which are able to oxidize and mineralize almost any organic molecule, yielding CO_2 and inorganic ions. Methods based on UV, H_2O_2/UV, O_3/UV, and other combinations use photolysis of H_2O_2 and ozone to produce the hydroxyl radicals, but generation of UV radiation by lamps or ozone production is expensive. So, future applications of these processes could be improved through the use of catalysis and solar energy. Therefore, research is focusing more and more on those AOPs which can be driven by solar irradiation, permitting solar detoxification and disinfection of water.

Introduction

Conventional methods of water disinfection and decontamination are often chemically, energetically, and operationally intensive, focused on large systems, and thus require considerable infusion of capital, engineering expertise, and infrastructure, all of which preclude their use in much of the world. Furthermore, intensive chemical treatments (such as those involving ammonia, chlorine compounds, hydrochloric acid, sodium hydroxide, ozone, permanganate, alum and ferric salts, coagulation and filtration aids, antiscalants, corrosion control chemicals, and ion-exchange resins and regenerants) and residuals resulting from treatment (sludge, brines, toxic waste) can add to the problems of contamination and salting of freshwater sources.

Rate constants (k_{OH}, $r = k_{OH}$ [•OH] C) for most reactions involving hydroxyl radicals in aqueous solution are usually on the order of 10^6 to 10^9 M^{-1} s^{-1}. They are also characterized by their nonselective attack, which is a useful attribute for wastewater treatment and solution of pollution problems. The versatility of the AOPs is also enhanced by the fact that there are different ways of producing hydroxyl radicals, facilitating compliance with the specific treatment requirements [1].

Heterogeneous photocatalysis and homogeneous photo-Fenton are based on the use of a wide-bandgap semiconductor and addition of H_2O_2 to dissolved iron salts, respectively, and irradiation with UV–VIS light [2]. Both processes are of special interest since sunlight can be used for them.

The overarching goal for the future of reclamation and reuse of water is to capture water directly from nontraditional sources such as industrial or municipal wastewaters and restore it. Municipal wastewaters are commonly treated by activated sludge systems that use suspended microbes to remove organics and nutrients, and large sedimentation tanks to separate the solid and liquid fractions. This level of treatment produces wastewater effluent suitable for discharge to surface waters or for restricted irrigation and some industrial applications. Current wastewater reuse systems use a conventional activated sludge process, followed by a microfiltration pretreatment of the secondary effluent, which has high quantities of suspended and dissolved solids. The effluent water still partially contains dissolved species and colloidal substances that act to foul the membranes of the subsequent RO (reverse osmosis) system used as a final barrier to contaminants in the product water. Futuristic direct reuse systems envisioned [3] involve only two steps: a single-stage membrane bioreactor (MBR) with an immersed nanofiltration membrane (obviating the need for an RO stage), followed by a photocatalytic reactor to provide an absolute barrier to pathogens and to destroy low-molecular-weight organic contaminants that may pass the nanofiltration barrier.

Industrial wastewater is often polluted by toxic or nonbiodegradable organic compounds. Alternatives to the conventional activated sludge treatment need to be employed. Among these, chemical oxidative treatments, and especially advanced oxidation processes (AOPs), are well known for their capacity for oxidizing and mineralizing almost any organic contaminant. Nevertheless, technical applications are still scarce [4]. As the process costs may be considered the main obstacle to their commercial application, several promising cost-cutting approaches have been proposed, such as integration of AOPs as part of a treatment train. It has been demonstrated that AOPs are able to enhance biodegradability of real wastewaters containing biorecalcitrant compounds [5], but it has been also pointed out that the process should be optimized by a proper selection of treatment time [6–8]. Operational conditions should be selected in a suitable range ensuring proper managing of real wastewaters of unpredictable composition. This coupled technology can be applied in industrial plants with difficult access to the municipal sanitation and sewage system, making possible the direct discharge of the effluent or its reutilization in industrial facilities. On the other hand, the correct operation of the system could very often permit the disposal of the pretreated wastewater in conventional sewage systems. In the typical basic process design approach, an AOP pretreats nonbiodegradable or toxic wastewater, and once biodegradability has been achieved, the effluent is transferred to a cheaper biological treatment.

The most important issue in water disinfection is, of course, safe drinking water. According to the WHO and UNICEF, polluted drinking water and lack of sanitation is responsible for the death of approximately 4,500–5,000 children every day, and one billion people still lack access to safe drinking water [9]. In addition to the well-known task of drinking-water disinfection, the second most critical issue is the disinfection of water for agriculture. Bearing in mind that the daily drinking-water requirement per person is only 2–4 L, it is often forgotten that it still takes 2,000–5,000 L of water to produce a person's daily food requirement [10]. Eighty percent of land cultivated worldwide is today still exclusively rainfed. Stored rainwater or surface water used for irrigation accumulates phytopathogens as phytopathogenic bacteria and fungi can be found almost everywhere. The plant and human pathogen *F. solani* has been reported as found almost everywhere, even in hospital water distribution systems [11]. Phytopathogens may be fought with organic disinfectants, also referred to as pesticides, which can be employed for disinfection of irrigation water, but this involves many negative aspects. Chlorine is used extensively, but has the drawback of the disinfection byproducts and resistance. Recent research on solar and solar photocatalytic disinfection attempts to combine sustainability with low cost, leading to an efficient disinfection method, not only for drinking water, but also for irrigation [12, 13].

The publications regarding the photocatalytic process rose continuously over the last years, surpassing

Solar Detoxification and Disinfection of Water. Figure 1
Publication treating photocatalysis and the share treating solar-driven photocatalysis (Source: www.scopus.com, 2010; search terms "photocatalysis" and "solar" within these results)

meanwhile a total number of more than 2,000 peer-reviewed publications per year in 2009. Though such a simple search does not necessarily include every single article correctly, it still serves to prove the general trend of an increasing interest of the scientific community. Figure 1 shows the evolution of these publication activities. Figure 1 also illustrates that much of the literature takes into account the possibility of driving the process with solar radiation. This fact is due to that a priori the photocatalytic process seems to be the most apt of all AOPs to be driven by sunlight. This chapter highlights some of the science and technology being developed to improve the solar photocatalytic disinfection and decontamination of water, as well as efforts to increase water supplies through the safe reuse of wastewater and adequate treatment of industrial wastewater.

Solar TiO_2 (Heterogeneous) Photocatalysis Applied to Water Decontamination

The heterogeneous solar photocatalytic detoxification process consists of making use of the near-ultraviolet band of the solar spectrum ($\lambda < 400$ nm), to photoexcite a semiconductor catalyst in contact with water and in the presence of oxygen. Some semiconductor catalysts can absorb above 400 nm. Oxidizing species (hydroxyl radicals, •OH, produced due to the photogenerated holes), which attack oxidizable contaminants, are generated, producing a progressive breakup of molecules yielding CO_2, H_2O, and diluted inorganic acids. The most important features of this process making it applicable to the treatment of contaminated aqueous effluents are:

- The process takes place at ambient temperature and without overpressure.
- Oxidation of the substances into CO_2 and other inorganic species is complete.
- The oxygen necessary for the reaction can be directly obtained from atmosphere.
- The catalyst is innocuous and can be reused or attached to different types of inert matrices.
- The energy for photoexciting the catalyst can be obtained from the sun.

Semiconductors (e.g., TiO_2, ZnO, Fe_2O_3, CdS, and ZnS) can act as sensitizers for light-induced redox processes due to their electronic structure which is characterized by a filled valence band and an empty conduction band. Absorption of a photon of energy greater than the bandgap energy leads to the formation of an electron/hole pair (Reaction 1). In the absence of suitable scavengers, the stored energy is dissipated within a few nanoseconds by recombination.

If a suitable scavenger or surface defect state is available to trap the electron or hole, recombination is prevented, and subsequent redox reactions (Reactions 2 and 3) may occur. The valence band holes are powerful oxidants (+1.0 to +3.5 V vs NHE depending on the semiconductor and pH), while the conduction band electrons are good reductants (+0.5 to −1.5 V vs NHE):

$$C \xrightarrow{h\nu} C(e^- + h^+) \quad (1)$$

$$h^+ + Red_2 \rightarrow Ox_2 \quad (2)$$

$$e^- + Ox_1 \rightarrow Red_1 \quad (3)$$

In the presence of a fluid (contaminated water), a spontaneous adsorption occurs (water and pollutant), and according to the redox potential of each adsorbate, an electron transfer proceeds toward acceptor molecules, whereas a positive hole is transferred to a donor molecule. Each ion formed subsequently reacts to form the intermediates and final products. Since the photonic excitation of the catalyst appears as the initial step of the activation of the whole catalytic system, being necessary that the photon has enough energy to be absorbed by the catalyst, not by the reactants. Subsequently, the activation of the process goes through the excitation of the solid, but not through that of the reactants. Furthermore, the oxidative species formed (in particular the hydroxyl radicals, $^{\bullet}OH$) react with the majority of organic substances (contaminants). For example, in aromatic compounds, the aromatic part is hydroxylated, and successive steps in oxidation/addition lead to ring opening. The resulting aldehydes and carboxylic acids are decarboxylated and finally produce CO_2. However, the important issue governing the efficiency of photocatalytic oxidative degradation is minimizing electron/hole recombination by maximizing the rate of interfacial electron transfer to capture the photogenerated electron and/or hole. This issue is discussed in more detail later.

Whenever different semiconductor materials have been tested under comparable conditions for the degradation of the same compounds, TiO_2 has generally been demonstrated to be the most active. Furthermore, TiO_2 is of special interest since it can use natural (solar) UV. This is because it has an appropriate energetic separation between its valence and conduction bands which can be surpassed by the energy content of a solar photon (see Table 1). Other semiconductor particles, for example, CdS or GaP, absorb larger fractions of the solar spectrum and can form chemically activated surface-bond intermediates, but unfortunately, these photocatalysts are degraded during the repeated catalytic cycles involved in heterogeneous photocatalysis. To date, evidence supports the idea that the $^{\bullet}OH$ is the main oxidizing specimen responsible for photooxidation of the majority of the organic compounds studied. In TiO_2, after absorption of near-ultraviolet radiation, $\lambda < 390$ nm, electron/hole pairs are generated. In order to avoid recombination of the pairs generated, if the solvent is oxidoreductively active (water), it also acts as a donor and acceptor of electrons. Thus, on a hydrated and hydroxylated TiO_2 surface, the holes trap $^{\bullet}OH$ radicals linked to the surface (Reaction 4). In any case, it should be emphasized that even trapped electrons and holes can rapidly recombine on the surface of a particle (Reaction 5). This can be partially avoided through the capture of the electron by preadsorbed molecular oxygen, forming a superoxide radical (Reaction 6):

$$\begin{aligned}&(TiO^{IV} - O^{2-} - Ti^{IV}) - OH_2 + h^+ \\ &\quad \rightarrow (TiO^{IV} - O^{2-} - Ti^{IV}) - {}^{\bullet}OH + H^+\end{aligned} \quad (4)$$

Solar Detoxification and Disinfection of Water. Table 1 Band position (water at pH = 1) for some common semiconductor photocatalyst. E_G bandgap energy

$$e^- + h^+ + TiO_2 \rightarrow TiO_2 + \text{heat or } h\nu \quad (5)$$

$$O_2 + e^- \rightarrow O_2^{\bullet -} \quad (6)$$

Degradation by photocatalysis has been most investigated in dimethoxybenzenes, halobenzenes, nitrobenzene, chlorophenols, nitrophenols, benzamide, aniline, etc., most of which are recognized as priority pollutants. In addition to these, several other types of molecules have also been investigated as substrates for photocatalytic degradation: haloaliphatics (trichloroethylene, tetrachloromethane, etc.), pesticides (triazines, organophosphorus, carbamates, phenoxyacids, organochlorines, chloronicotinics, etc.), surfactants, dyes, etc. Until now, the absence of total mineralization has been observed only in s-triazine herbicides, for which the final product obtained was essentially 1,3,5-triazine-2,4,6, trihydroxy (cyanuric acid), which is, fortunately, nontoxic. Special attention has recently been given to the so-called emerging contaminants, mostly unregulated compounds that may be candidates for future regulation depending on research on their potential effects on health and monitoring data regarding their occurrence. Particularly relevant examples of such emerging compounds are those which do not need to persist in the environment to cause a negative effect because their high transformation/removal rates can be compensated by their continuous introduction into the environment [14]. The solar photocatalytic degradation of these new environmental contaminants (pharmaceuticals, antibiotics, analgesics, steroids, hormones, MTBE, cyanotoxins, etc., and their hydrolysis/photolysis reaction intermediates), many of them until recently unknown, is the focus of much research [15].

In photocatalysis, transformation of the parent organic compound is desirable in order to eliminate its toxicity and persistence, but the principal objective is to mineralize all pollutants. The effectiveness of degradation is not demonstrated only because the entire initial compound is decomposed. Reactants and products might be lost (evaporation, adsorption on reactor components, etc.) which introduces uncertainty in results. The mineralization rate is determined by monitoring inorganic compounds, such as CO_2, Cl^-, SO_4^{2-}, NO_3^-, PO_4^{3-}, etc. For chlorinated molecules, Cl^- ions are easily released in the solution and are the first of the ions appearing during the photocatalytic degradation (see Fig. 2). Nitrogen-containing molecules are mineralized mostly into NO_3^- and NH_4^+. Ammonium ions are relatively stable, and the proportion depends mainly on the oxidation stage of organic nitrogen and irradiation time [16]. By comparing the sequence of appearance, NH_4^+ appears as the primary product with respect to NO_3^- in the case of amine compounds. The nitrogen atoms in the amino groups can lead to NH_4^+ ions by successive attacks by hydrogen-containing species. The total amount of nitrogen-containing ions present in the solution at the end of the experiments is usually lower than that

Solar Detoxification and Disinfection of Water. Figure 2
Degradation until complete mineralization of a model contaminant (pentachlorophenol) dissolved in water by •OH radicals

expected from stoichiometry, indicating that N-containing species remain adsorbed in the photocatalyst surface or most probably that significant quantities of N_2 and/or NH_3 have been produced and transferred to the gas phase. The formation of N_2 in azo bounds can be accounted for by the same processes responsible for NH_4^+ formation [17]. N_2 evolution constitutes the ideal case for a decontamination reaction involving totally innocuous nitrogen-containing final product.

Organophosphorus contaminants produce phosphate ions. However, in the pH range used (usually >4), phosphate ions remain adsorbed on TiO_2. This strong adsorption somewhat inhibits the reaction rate, though it is still acceptable. The release of SO_4^{2-} can be accounted by an initial attack by a photoinduced $^{\bullet}OH$ radical. In all the studies, the formation of SO_4^{2-} was always observed, and in most cases, its stoichiometric formation was found in the final steps of the photoreaction when organic intermediates were still present. Initial rate was high, indicating that SO_4^{2-} ions are initial products, directly resulting from the initial attack on the sulfonyl group. Nonstoichiometric formation of sulfate ions is usually explained by a strong adsorption on the photocatalyst surface. This strong adsorption could partially inhibit the reaction rate which, however, remains acceptable. Sulfate, chloride, and phosphate ions, especially at concentrations greater than 1 mM, can reduce the rate due to the competitive adsorption at the photoactivated reaction sites.

Treatment of industrial wastewater seems to be one of the most promising fields of application of solar photocatalysis. There is no general rule at all, each case being completely different [18]. Consequently, preliminary research is always required to assess potential pollutant treatments and optimize the best option for any specific problem, on a nearly case-by-case basis. Reaction 7 generally holds true for an organic compound of general formula $C_nH_mO_p$:

$$C_nH_mO_p + \left(\frac{(m-2p)}{4} + n\right)O_2 \rightarrow nCO_2 + \frac{m}{2}H_2O \tag{7}$$

The oxidation of carbon atoms into CO_2 is relatively easy. In general, at low reactant levels or for compounds which do not form important intermediates, complete mineralization and reactant disappearance proceed with similar half lives, but at higher reactant levels where important intermediates occur, mineralization is slower than the degradation of the parent compound. However, before TiO_2 photocatalytic treatment can be proposed as a general and trouble-free method, it is required that the chemistry of various classes of pollutants under these conditions is known in detail. Since the chemistry of such processes is complex, careful analytical monitoring using different techniques is essential in order to control all transformation steps, to identify harmful intermediates, and to understand and interpret the reaction mechanism. The assessment of pollutant disappearance in the early steps is not sufficient to ensure the absence of residual products because the heterogeneous photocatalytic treatment may give rise to a variety of organic intermediates which can themselves be toxic, and in some cases, more persistent than the original substrate [19].

From an analytical viewpoint, the task that entails the most difficulty is, without doubt, qualitative and quantitative evaluation of the intermediates or degradation products (DPs). As hydroxyl radicals are not selective in their attacks, numerous DPs form on the path toward complete mineralization. There are five main types of DPs:

- Hydroxylated and dehalogenated products, the latter of these derived from the loss of the halogenated substitute in the original contaminant, if it had one
- Products from the oxidation of the alkali chain, if it had one
- Products derived from the opening of the aromatic ring in aromatic contaminants
- Products of decarboxylation
- Products of isomerization and cyclation

The chemical analysis of these complex reaction mixtures is difficult, so that in the majority of the cases, not much attention is paid to their identification and analytical evaluation is limited to tracing the disappearance of the initial pollutant, combined with following decrease in TOC and the appearance of inorganic ions. Thus, the kinetic degradation of contaminants and the mineralization rate during the process are evaluated. However, a greater knowledge of the DPs originated would be necessary. It may be

observed in Fig. 3 the different DPs with high molecular weight appearing during photocatalytic treatment at short treatment time. From here on, they begin to decrease and carboxylic acids appear.

The basic parameters (necessary for relevant information on process kinetics and assure consistent results) to be evaluated are:

- Mineralization, as described below.
- Concentration of the original pollutant. Use of liquid chromatography with UV detection (LC-UV) is recommended for this as the most reliable and versatile technique for analysis of organic pollutants dissolved in water.
- Concentration of inorganic ions. In this case, liquid chromatography with electric conductivity detection (LC-IC) is recommended. This analytical method also makes it possible to determine low-molecular-weight carboxylic acids, which assists in establishing the degradation pathway of the compounds treated since these acids are usually the last step before pollutant mineralization. The most common are formic, acetic, oxalic, glycolic, propanoic, and pyruvic acid, etc.

A complete mass balance of photocatalytic degradation processes is imperative and is generally reported in studies that envisage application of photocatalytic water treatment. The determination of total organic carbon (TOC) and/or the measurement of the chemical oxygen demand (COD) of the irradiated solution are generally used for monitoring the mineralization. It is appropriate to analyze the chemical oxygen demand (COD) when CO_2 or TOC determination is unavailable since it is a cheaper method. However, the information that it provides on mineralization of the

Solar Detoxification and Disinfection of Water. Figure 3
Photodegradation products identified during the TiO_2 photocatalysis of trimethoprim (TMP)

compounds is not as reliable as TOC because COD analyses are usually not accurate for pollutant concentrations in the order of milligrams per liter (very common in photocatalysis) and because oxidizable inorganic species cannot be distinguished from the organic pollutants.

Therefore, the analysis of reaction mixtures containing one or several contaminants and their DPs requires analytical methods that enable the separation and identification of the large number of compounds, with very different chemical properties present in a wide interval of concentrations. In practice, this is possible through the use of sophisticated analytical tools, such as gas chromatography coupled with mass spectrometry (GC-MS) and liquid chromatography coupled also to mass spectrometry (LC-MS). These methods or combinations of them can confirm the identity of the DPs present in a reaction mixture; however, they require specific expertise and the process is usually time consuming. In the last 10 years, analytical instrumentation and techniques have undergone rapid development. Very sophisticated equipment and techniques, especially in the field of GC-MS and LC-MS, have been developed to enable efficient determination of organic compounds [20, 21].

Fundamental Parameters Affecting Kinetics in Solar TiO_2 (Heterogeneous) Photocatalysis Applied to Water Decontamination

Mass of Catalyst

TiO_2 is often used as a suspension, and the rate of photomineralization is generally found to increase with catalyst concentration toward a limiting value at high TiO_2 concentration. This limit depends on the geometry and working conditions of the photoreactor and is for a definite amount of TiO_2 in which all the particles, that is, all the surface exposed, are totally illuminated. When catalyst concentration is very high, after travelling a certain distance on an optical path, turbidity impedes further penetration of light in the reactor. In any given application, this optimum catalyst mass has to be found in order to avoid excess catalyst and ensure total absorption of efficient photons [22, 23]. There are a number of studies in the literature on the influence of catalyst concentration on process efficiency. The results are very different, but from all of them, it may be deduced that radiation incident on the reactor and path length inside the reactor are fundamental in determining the optimum catalyst concentration. In the case of solar photoreactors where the path length is several centimeters long, the appropriate catalyst concentration is several hundreds of milligrams per liter. In this case, it is very clear that the highest rate (i.e., lowest collector area per mass of catalyst) is attained at lower catalyst concentrations when the photoreactor diameter is increased. In the case of the heterogeneous process with TiO_2 in suspension, sedimentation and deposition of the catalyst along the hydraulic circuit must also be avoided, so that turbulent flow in the reactor must be guaranteed [24]. Turbulent flow makes pressure loss an important parameter that can condition design, especially in the case of an industrial plant with long reactor tube lengths. For these reasons, diameters of less than 20–25 mm are not feasible. On the other hand, diameters over 50–60 mm are not considered practical. Furthermore, every photoreactor design must guarantee that all the useful incoming photons are used and do not escape without having intercepted a particle in the reactor.

Although TiO_2 suspensions absorb solar photons with less than 390–400 nm wavelengths, there is also a strong light-scattering effect due to particles. Both effects must be considered in determining the optimum catalyst load as a function of optical path length in the photoreactor. Wavelengths where the catalyst does not absorb light are better for determining the optimum catalyst concentration as a function of light-path length. Under these conditions, measurement of photon losses is only affected by turbidity and it is easy to evaluate the effect of the photoreactor diameter. In Fig. 4, where these results are shown for different photoreactor designs, it may be seen how solar photoreactors present lower optimum catalyst concentration, compared with artificial light devices.

If the lamp is inside the reactor and coaxial with it (Fig. 4a), the optimum catalyst concentration is very high (on the order of several grams per liter). On the other hand, the optimum catalyst concentration is medium (1–2 g/l) if the lamp is outside (Fig. 4b). In the case of solar photoreactors (Fig. 4c), the appropriate catalyst concentration is several hundreds of milligrams per liter. In any case, these are only

Solar Detoxification and Disinfection of Water. Figure 4
Different photoreactor designs and zones of radiation penetration when illuminated in different ways. The influence of catalyst concentration on the rate of photocatalysis in the different photoreactors is also shown

approximations based on the results obtained by different authors, and because of all of the above, it is always necessary to find out, experimentally, the optimum catalyst concentration for the solar collector studied. That is, the minimum concentration of photocatalyst at which the maximum reaction rate is obtained.

pH

The pH of the aqueous solution significantly affects TiO_2, including the charge on the particles, the size of the aggregates it forms, and the positions of the conductance and valence bands. It is somewhat surprising, therefore, that the rate of photocatalytic mineralization is not usually found to be strongly dependent upon pH between values ranging from 4 to 10. To work outside these values is not logical due to environmental and economical reasons, if the wastewater pH would need to be adjusted. Often, the pH of industrial wastewater can be very acidic or basic. In this case, the effect of pH on TiO_2 photocatalytic efficiency should be taken into account as the process could be enhanced, varying the pH by simple/cheap methods as, for example, mixing different streams.

The pH at which the surface of an oxide is uncharged is defined as the zero point charge (pH_{zpc}), which for TiO_2 depends on the production method ($4.5 < pH_{zpc} < \sim 7$). Above and below this value, the catalyst is negatively or positively charged according to Reactions 8 and 9:

$$-\,TiOH_2^+ \leftrightarrow TiOH + H^+ \tag{8}$$

$$-\,TiOH \leftrightarrow -TiO^- + H^+ \tag{9}$$

The equilibrium constants of these reactions [25] are $pK_{TiOH2+} = 2.4$ and $pK_{TiOH} = 8.0$, the abundance of all the species as a function of pH being $-\,TiOH \geq 80\%$ when $3 < pH < 10$, $-TiO^- \geq 20\%$ when $pH > 10$, and $-\,TiOH_2^+ \geq 20\%$ when $pH < 3$. A very important feature of photocatalysis that must be taken into account when it is to be used for decontamination of water is that during the reaction, a multitude of intermediate products are produced (see Fig. 3) that may behave differently depending on the pH of the solution.

To use only the rate of decomposition of the original substrate could yield an erroneous pH as the best for contaminant degradation. Therefore, a detailed analysis of the pH conditions should include not only the initial substrate but also the rest of the compounds produced during the process. Measurement of an overall parameter as TOC (or COD, or toxicity, or biodegradability, etc.) should be used for choosing the optimum pH or at least to determine the effect of pH on the behavior of the chosen key parameter.

The size of the aggregates formed by TiO_2 particles is also affected by pH. Mean particle-size measurements have been found to be constant at pH far from pH_{zpc}. Several hundred nanometer sizes increase to 2–4 μm when dispersion reaches pH_{zpc} [26]. The zero surface charge yields zero electrostatic surface potential that cannot produce the interactive rejection necessary to separate the particles within the liquid. This induces a phenomenon of aggregation, and TiO_2 clusters become larger. This effect is clearly related to the capability of the suspension for transmitting and/or absorbing light. Furthermore, larger clusters sediment more quickly than small particles; thus, the agitation necessary to maintain good catalyst uniformity must be more vigorous. Therefore, pH close to zero point charge should be avoided in order to not promote TiO_2 particle aggregation.

Temperature

Because of the photonic activation, the photocatalytic systems do not require heating and are operating at room temperature. The true activation energy is nil, whereas the apparent activation energy is often very small (a few kJ/mol) in the medium temperature range (between 20°C and 80°C). However, at very low temperatures (below 0°C), the apparent activation energy increases. The desorption of the final product becomes the rate-limiting step and trends to the heat of adsorption of the product. On the other hand, when temperature increases above 80°C and approaching to the boiling point of water, the exothermic adsorption of reactants becomes disfavored and tends to become the rate-limiting step. Correspondingly, the activity decreases, and the apparent activation energy becomes negative. As a consequence, the optimum temperature is generally comprised between 20°C and 80°C.

This absence of heating is attractive for photocatalytic reactions carried out in aqueous media and, in particular, for photocatalytic water purification. There is no need to waste energy in heating water which possesses a high heat capacity. It is also necessary to take into account that the solubility of oxygen decreases with increasing temperature, affecting therefore to the kinetics described in section "Concentration of Oxygen." Temperature does become a factor in photocatalytic disinfection and as such is commented in section "Solar Disinfection and Photocatalytic Disinfection." This behavior can be easily explained within the frame of the Langmuir–Hinshelwood mechanism described above. The decrease in temperature favors adsorption, which is a spontaneous exothermic phenomenon; θ_x approaches to unity; and KC becomes >> 1. The lowering in T also favors the adsorption (K_P) of the final reaction products, inhibiting the reaction as the term $K_P C_P$ appears in the denominator of Eq. 10. Above 80°C, the adsorption of reactants is disfavored and KC becomes <<1, being $r = k_{ap}C$.

In the photomineralization of organic pollutants sensitized by TiO_2, it has been traditionally reported that the initial rate of disappearance of the pollutant (X) fits a Langmuir–Hinshelwood (L–H) kinetic scheme. According to the L–H model (Eq. 10), the reaction rate (r) is proportional to the fraction of surface of photocatalyst covered by the substrate (θ_x), k_r the reaction rate constant, C the concentration of species X, and K the reactant adsorption constant:

$$r = -\frac{dC}{dt} = k_r\,\theta_x = \frac{k_r\,KC}{1 + KC} \tag{10}$$

As oxidation proceeds, less and less of the surface of the TiO_2 particles is covered as the contaminant is decomposed. Evidently, at total decomposition, the rate of degradation is zero, and a decreased photocatalytic rate is to be expected with increasing illumination time. Most authors agree that, with minor variations, the expression for the rate of photomineralization of organic substrates with irradiated TiO_2 follows the L–H law. Although the L–H isotherm has been rather useful in modeling the process, it is generally agreed that both rate constants and orders are only "apparent" [27–29]. They serve to describe the rate of degradation, and may be used for reactor optimization,

but they have no physical meaning, and may not be used to identify surface processes. Thus, while not an useful tool for describing the active species involved in oxidation, engineers and solar designers seem to have a common understanding of the usefulness of the unmodified L–H model.

Traditionally, K is taken to represent the Langmuir absorption constant of the species X on the surface of TiO_2, and k_r is a proportionality constant which provides a measure of the intrinsic reactivity of the photoactivated surface with X. It is found that k is proportional to Φ_e^n, where Φ_e is the rate of effective (able to form electron/hole pairs) light absorption, and n is a power term which is less than 1 or 1, at high or low light intensities, respectively. In section "Radiant Flux," the effect of Φ on the reaction rate is discussed in more detail.

Radiant Flux

Since 1990, there has been a clarification of the kind of solar technology which should be involved in photocatalysis. The question was if it is necessary to concentrate the radiation for the photocatalysis technology and if a nonconcentrating collector can be as efficient as concentrating ones. Initially, it was thought that concentrating collectors were the ideal alternative, and in fact, the first large pilot plants operated were using them. However, their high cost and the fact that they can only operate with direct solar radiation (this implies their location in highly irradiated areas with few cloud cover) led to consider static nonconcentrating collectors as an alternative [30]. The reason of using one-sun systems for water treatment is firmly based on two factors: first, the high percentage of UV photons in the diffuse component of solar radiation, and second, the low-order dependence of rates on light intensity.

It has been shown, for all types of photocatalytic reactions, that the rate of reaction is proportional to the radiant flux (Φ). This confirms the photoinduced nature of the activation of the catalytic process, with the participation of photoinduced electrical charge (electrons and holes) to the reaction mechanism. However, above a certain value, the reaction rate becomes proportional to Φ^n ($0 > n > 1$). This modification does not seem to happen at well-established radiation intensity, as different researchers obtain different results. It is presumable that the experimental conditions affect significantly, but it has been stated that with a typical solar UV flux of 20–30 Wm^{-2} (0.2–0.3 mol photons m^{-2} h^{-1} in the 300–400 nm), the concentration of sunlight (R_C) on the photoreactor using specific solar concentrating collectors ($R_C = A/2\pi r$, being A the collector aperture width and r the reactor tube radius) is not convenient as reaction rate is usually proportional to $\Phi^{0.5}$. A practical appraisal to this statement is that more than 50 W (<400 nm) per square meter of photoreactor (being tubular or flat-plate) will produce a loss of photonic efficiency. Most authors [31–34] impute the transition of $r = f(\Phi)$ to $r = f(\Phi^{0.5})$, to the excess of photogenerated species (e^-, h^+, and $^{\bullet}OH$). When Φ is very high, a large number of holes and electrons are generated. As the reaction rate depends on the amount of hydroxyl radicals present, and these are generated in the holes (see Eqs. 4, 5), then r is proportional $\Phi^{0.5}$ when Φ is high. Under these conditions, the quantum yield diminishes because the rate of electron/hole formation becomes greater than the photocatalytic rate, which favors the electron/hole recombination.

At much higher radiation intensities, another transition from $r = f(\Phi^{0.5})$ to $r = f(\Phi^0)$ is produced. At this moment, the photocatalytic reaction leaves its dependence on the received radiation, to depend only on the mass transfer within the reaction. So, the rate is constant, although the radiation increases. This effect can be due to different causes, as can be the lack of electrons scavengers (i.e., O_2), or organic molecules in the proximity of TiO_2 surface and/or excess of products occupying active centers of the catalyst, etc. In practical applications, these phenomena are observed more frequently when working with supported catalyst and/or at low agitation level. This implies low catalyst surface in contact with the liquid and smaller turbulence. Thus, the contact of reactants with the catalyst and the diffusion of products from the proximity of the catalyst to the liquid are not favored.

Concentration of Oxygen

In semiconductor photocatalysis for water purification, the pollutants are usually organic, and therefore, the overall process can be summarized by Eq. 11. Given the reaction stoichiometry of this equation, there is no

photomineralization unless O_2 is present. The literature provides a consensus regarding the influence of oxygen. Oxygen is necessary for complete mineralization and does not seem to be competitive with other reactives during the adsorption on TiO_2 since oxidation takes place at a different location from where reduction occurs (see Reactions 4–6). The concentration of oxygen also affects the reaction rate, but it seems that the difference between using air or pure oxygen is not drastic. In an industrial plant, it would be purely a matter of economy of design. It has been reported that the rate of oxidation was independent of oxygen concentrations below air saturation values, suggesting also that the mass transfer of oxygen to the surface could be rate limiting:

$$\text{organic pollutant} + O_2 \xrightarrow[\text{ultra-bandgap energy}]{TiO_2} CO_2 + H_2O + \text{mineral acids} \tag{11}$$

Due to its availability in water, adsorbed oxygen serves as the electron acceptor in semiconductor photocatalysis. Rate equations (see Fig. 5) have been derived assuming a Langmuir adsorption of oxygen onto the titanium dioxide surface. The role of oxygen may not only be that of an electron acceptor. Oxygen, for instance, may be involved in the formation of other oxidative species (superoxide, hydrogen peroxide, hydroxyl radicals), in the prevention of reduction reactions, in the stabilization of radical intermediates, mineralization, and direct photocatalytic reactions.

It is generally assumed that oxygen adsorbs on titania from the liquid phase, where it is dissolved following Henry's law. If the oxygen is regularly supplied, it can be assumed that its coverage at the surface of titania is constant and can be integrated into the apparent rate constant (k_{ap}). In most kinetic studies, the observed variation of the rate of photomineralization as a function of concentration of oxygen is described as shown in Fig. 5, where plots of r versus $\%O_2$ during the photodegradation of a contaminant by TiO_2 photocatalysis are illustrated. Thus, increasing the oxygen concentration in aqueous solution from air saturated (21% O_2) to O_2 saturated (100% O_2) conditions will typically increase the rate by only a small quantity.

Solar Photo-Fenton

For the treatment of industrial wastewater, Fenton and Fenton-like processes are probably among the most

Solar Detoxification and Disinfection of Water. Figure 5
Plots of initial relative rate (r) versus concentration of oxygen ($\%O_2$)

applied advanced oxidation processes. The first proposals for wastewater treatment applications were reported in the 1960s. Quite recent reviews give good overviews of the Fenton chemistry [35, 36]. Yet, it was not until the early 1990s when the first works of the application of the photo-Fenton process (or photoassisted/light-enhanced Fenton process) for the treatment of wastewater were published. Since then, the publication activities regarding the photo-Fenton process rose continuously, surpassing 700 peer-reviewed publications up-to-date (source: www.scopus.com, 07.08.2010; search criteria "photo-Fenton" and "solar photo-Fenton"). Much of the literature treating the photo-Fenton process takes into account the possibility of driving the process with solar radiation. This fact is due to that a priori the photo-Fenton process seems to be the most apt of all AOPs to be driven by sunlight because soluble iron–hydroxy and especially iron–organic acid complexes absorb even part of the visible light spectrum, not only ultraviolet radiation. Consequently, the photo-Fenton system is a very efficient reaction system for the generation of radicals available for oxidative processes.

Hydrogen peroxide is decomposed to water and oxygen in the presence of iron ions in aqueous solution in the Fenton reaction, Eq. 12, which was first reported by H.J.H. Fenton in 1894 [37]. Mixtures of ferrous iron and hydrogen peroxide are called Fenton reagent. If ferrous is replaced by ferric iron, it is called Fenton-like reagent. Equations 12–14 summarize briefly the reactions of ferrous iron, ferric iron, and hydrogen peroxide in the absence of other interfering ions and organic substances. The regeneration of ferrous iron from ferric iron by Eqs. 13, 14 is the rate-limiting step in the catalytic iron cycle, if iron is added in small amounts:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH \tag{12}$$

$$Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + HO_2^{\bullet} + H^+ \tag{13}$$

$$Fe^{3+} + HO_2^{\bullet} \rightarrow Fe^{2+} + O_2 + H^+ \tag{14}$$

If organic substances (quenchers, scavengers, or in the case of wastewater treatment pollutants) are present in the system $Fe^{2+}/Fe^{3+}/H_2O_2$, they react in many ways with the generated hydroxyl radicals. Yet, in all cases, the oxidative attack is electrophilic and the rate constants are close to the diffusion-controlled limit. There is one great setback of the Fenton method. Especially when the treatment goal is the total mineralization of organic pollutants, carboxylic intermediates cannot be further degraded. Carboxylic and dicarboxylic acids are known to form stable iron complexes, which inhibit the reaction with peroxide [38]. Hence, the catalytic iron cycle reaches a standstill before total mineralization is accomplished, Eq. 15:

$$Fe^{3+} + nL \rightarrow [FeL_n]^{x+} \xrightarrow{H_2O_2,\text{dark}} \text{no further reaction}$$
$$L: \text{mono} - \text{and dicarboxylic acids} \tag{15}$$

The primary step of the photoreduction of dissolved ferric iron is a ligand-to-metal charge-transfer (LMCT) reaction. Subsequently, intermediate complexes dissociate as shown in Reaction 16 [39]. The ligand can be any Lewis base able to form a complex with ferric iron (OH^-, H_2O, HO_2^-, Cl^-, R–COO^-, R–OH, R–NH_2, etc.). Depending on the reacting ligand, the product may be a hydroxyl radical such as in Eqs. 17 and 18 or another radical derived from the ligand:

$$[Fe^{3+}L] + h\nu \rightarrow [Fe^{3+}L]^* \rightarrow Fe^{2+} + L^{\bullet} \tag{16}$$

$$[Fe(H_2O)]^{3+} + h\nu \rightarrow Fe^{2+} + {}^{\bullet}OH + H^+ \tag{17}$$

$$[Fe(OH)]^{2+} + h\nu \rightarrow Fe^{2+} + {}^{\bullet}OH \tag{18}$$

$$[Fe(OOC-R)]^{2+} + h\nu \rightarrow Fe^{2+} + CO_2 + R^{\bullet} \tag{19}$$

$$Fe(C_2O_4)_3{}^{3-} + h\nu \rightarrow Fe^{2+} + 2\,C_2O_4{}^{2-} + C_2O_4{}^{\bullet-} \tag{20}$$

Depending on the ligand, the ferric iron complex has different light absorption properties, and Reaction 16 takes place with different quantum yields and also at different wavelengths. Consequently, the pH plays a crucial role in the efficiency of the photo-Fenton reaction because it strongly influences which complexes are formed. Thus, pH 2.8 was frequently postulated as an optimum pH for photo-Fenton treatment because at this pH, precipitation does not take place yet and the dominant iron species in solution is $[Fe(OH)]^{2+}$, the most photoactive ferric iron–water complex. In fact, as shown in its general form in

Eq. 16, ferric iron can form complexes with many substances and undergo photoreduction. Of special importance are carboxylic acids because they are frequent intermediate products in an oxidative treatment. Such ferric iron–carboxylate complexes can have much higher quantum yields than ferric iron–water complexes. It is therefore a typical observation that a reaction shows an initial lag phase, until intermediates are formed, which can regenerate more efficiently ferrous iron from ferric iron accelerating the process. This can either happen through a photochemical pathway, Eq. 19, a thermal pathway, or a combination of both.

Fe(III) complexes present in mildly acidic solution, such as $Fe(OH)^{2+}$ absorb light appreciably in the UV and into the visible region. The quantum yield for Fe^{2+} formation in Eq. 17 is wavelength-dependent. It is 0.14–0.19 at 313 nm and 0.017 at 360 nm [40]. Fe(III) may complex with certain target compounds or their by-products. These complexes typically have higher molar absorption coefficients in the near-UV and visible regions than the aquo complexes. Polychromatic quantum efficiencies in the UV-visible range from 0.05 to 0.95 are common [36]. Fe(III)–oxalate complexes (Eq. 20) are efficient up to 500 nm (quantum efficiency 1.0–1.2).

Effect of pH

The need for acidification in the photo-Fenton process is often outlined as one of its major drawbacks. Not only does this mean additional cost through the consumption of reagents for acidification and subsequent neutralization but also an increase of the treated water's salt load. A pH of 2.8 avoids iron precipitation (at least under low to moderate iron concentration below approximately 1 mM) but maximizes the concentration of mono- and dihydroxylated iron(III) aquo complexes, which absorb UV light more efficiently than the nonhydroxylated iron(III) complexes. This was accepted by many authors as a matter of fact, and henceforth, many publications appeared applying this pH (see Fig. 6). Usually, the reduction of ferric iron is the rate-limiting step in Fenton and photo-Fenton applications. Photoreduction of ferric iron complexes (Eqs. 16–19) takes place at longer wavelengths, when aquo and hydroxyl ligands are replaced with stronger complexing agents. Hence, if present, upon irradiation with sunlight, these complexes contribute more to the photoreduction than the aquo and hydroxyl complexes. Consequently, one must state that the early explanation for an optimum pH of 2.8 based on the

Solar Detoxification and Disinfection of Water. Figure 6
Mineralization (*DOC* dissolved organic carbon) by photo-Fenton of a model contaminant under solar irradiation at pH = 2.8 and at neutral pH

absorbance spectra of different aquo and hydroxyl ferric iron complexes seems only plausible in the absence of complexing agents. This is seldom the case, as carboxylic acids are formed in the oxidation process. Hence, the only real constraint seems to be the need of avoiding iron precipitation.

Effect of Iron Concentration and Iron Source

One of the principal characteristics of a photoreactor is its optical path length, for example, in the case of a tubular photoreactor, the tube diameter. A ray of light is attenuated along the optical path length as a function of the solution's extinction coefficient, which is closely related to the iron concentration. In general, the solar photoreactor constitutes a substantial part of the investment cost of the installation. Hence, one aim in the design of a photoreactor is that nearly the whole volume of the photoreactor is illuminated. A too-high iron concentration generates dark zones in the photoreactor because the incident ray is attenuated too strongly along the optical path length. The inner filter effects present in the solution are another important issue regarding the effect of iron concentration on the reaction rate. Inner filter effects are the competitive absorption of photons by other light-absorbing species, usually the contaminants present in the wastewater.

Consequently, one may state that iron concentration optimization must take into account the solar collector geometry and the inner filter effects. Also, to reduce inner filter effects, sunlight seems an ideal irradiance source. This ability to make use of photons of a wavelength beyond the UV region may also be one of the main reasons why photo-Fenton compares favorably to TiO_2 photocatalysis, when applied to highly colored wastewaters. Only logically following then is that another strategy to overcome inner filter effects is procuring iron complexes that absorb at higher wavelengths than the contaminants present in wastewater, which is part of the reason why applying iron sources containing already iron chelating ligands have been proposed, such as ferric oxalate [41], ferric citrate [42], or also other chelating agents [43]. Whereas there are several obvious advantages, there are also additional costs for adding the chelating agent, as the chelating agent is being oxidized as well more hydrogen peroxide ought to be needed to abate the target contamination.

Figure 7 shows mineralization of a mixture of five pesticides at three Fe^{2+} concentrations and the

Solar Detoxification and Disinfection of Water. Figure 7
Mineralization of a pesticide mixture at different Fe^{2+} concentrations, with H_2O_2 consumed during photo-Fenton treatment

Solar Detoxification and Disinfection of Water. Table 2 Zero-order kinetic constants (mg/L min) for each pesticide in the mixture treated by photo-Fenton shown in Fig. 7

Compounds	Fe^{2+}(mg/L)			Fe^{3+}(mg/L)		
	5	20	55	5	20	55
Oxamyl	0.47	1.48	3.62	0.29	1.34	2.50
Methomyl	0.11	0.40	0.55	0.10	0.36	0.47
Imidacloprid	0.11	0.44	1.08	0.10	0.41	0.69
Pyrimethanil	0.24	0.89	0.99	0.24	0.75	1.14
Dimethoate	0.32	0.99	1.69	0.39	1.16	1.56

corresponding hydrogen peroxide requirements during the processes [44]. The results were very similar to those with Fe^{3+}, especially at low iron concentrations. No significant difference in DOC was observed between Fe species, although this was not the case for degradation of each individual pesticide, as discussed later (see Table 2). Fe^{2+} salt is rapidly converted to Fe^{3+} if there is excess H_2O_2 (during the first seconds after adding H_2O_2), but the $^{\bullet}OH$ produced by Fenton reaction (Eq. 12) is not enough for significant oxidation of organics. When Fe^{3+} salt is used, it is reduced to Fe^{2+}, mainly by solar irradiation and by H_2O_2 (Eqs. 17 and 18). As the system behaves independently of the initial oxidation state of iron, ferrous iron cannot usually be distinguished from ferric iron by the reaction mechanism. However, in practice, differences in degradation rates may be observed. The presence of Fe^{2+} promotes an initial rapid degradation phase. The extent of this phase depends on the Fe/contaminant molar ratio. On the contrary, when Fe^{3+} is the initial iron source, the oxidation rate is slower than observed with Fe^{2+}, probably due to the fact that as Fe^{3+} is reduced to Fe^{2+}, the free radicals are generated more slowly. It is worth mentioning that with 5 mg/L of iron, treatment is noticeably less efficient (slower pesticide degradation, longer time required for any substantial mineralization, and more hydrogen peroxide consumed). This is because when the iron concentration is very low, H_2O_2 is consumed by less desirable reactions, such as Reactions 13, 21, and 22.

There were no significant differences between the other two iron concentrations (20 mg/L and 55 mg/L), although, as expected, results were slightly better with 55 mg/L. This can be explained because, due to the solar photoreactor design, iron concentration is enough to absorb all the solar irradiation in both cases. Therefore, Reactions 16–19 are maximized permitting quick regeneration of the ferrous ions. Under these conditions, the amount of absorbed photons is quite similar at 20 and 55 mg/L of Fe in a solar photoreactor with a 5-cm light-path length [45]. It should be noticed that the higher the concentration of iron, the fewer photons reach the axis of the photoreactor. However, it may also be said that as iron concentration increases, less hydrogen peroxide is needed for the same degradation. This is because in the presence of higher iron concentrations, the process is accelerated by two added benefits. Firstly, the photocatalytic regeneration of ferrous iron from ferric iron is faster, and there are always ferrous ions available to consume H_2O_2 and produce hydroxyl radicals. H_2O_2 is also more efficient, as it is mainly consumed in "useful" reactions. When the process is too slow, part of the H_2O_2 is decomposed into molecular oxygen and water but does not participate in the oxidation of the polluting molecules. Equations 21–23 show some simultaneous inefficient reactions occurring in the matrix when the hydrogen peroxide concentration in the solution is too high:

$$2H_2O_2 \rightarrow 2H_2O + O_2 \tag{21}$$

$$^{\bullet}OH + H_2O_2 \rightarrow H_2O + HO_2^{\bullet} \tag{22}$$

$$HO_2^{\bullet} + {}^{\bullet}OH \rightarrow H_2O + O_2 \tag{23}$$

Table 2 shows the zero-order kinetic constants for each pesticide with regard to photo-Fenton degradation of the commercial pesticide mixture shown in Fig. 7, employing both iron species at the three tested

concentrations. As expected, the kinetic constants increase with iron concentration and more so with Fe^{2+} than with Fe^{3+} due to the initial fast degradation phase explained above. This effect becomes more noticeable as the iron concentration rises (higher Fe/contaminant molar ratio). It might therefore be concluded that when the main purpose is to substantially reduce the organic content of wastewater, it is irrelevant which species of iron is used as long as its concentration is not too high (mM range). The same is true when the reaction time is expected to be longer than a few minutes.

Effect of Temperature

Increasing temperature always has a beneficial effect on reaction kinetics [46, 47], for example, by about five times by raising temperature from 20°C to 50°C. This can be explained by looking at the thermal reactions involved in the reduction of ferric iron, particularly Eqs. 13, 14, as opposed to the photoreduction of ferric iron. Whereas in the thermal pathway hydrogen peroxide is consumed for the reduction of ferric iron without producing hydroxyl radicals, in the photoreduction pathway, hydrogen peroxide is not consumed. This seems an obvious and easy explanation, but normally, the issue becomes complicated when other reactions are involved. However, a fast, significant loss of dissolved iron could be observed at 50°C, decreasing the degradation rate dramatically due to the reduction in the catalyst concentration, which limits the process [48]. Obviously, the decreased catalyst concentration had a negative effect on the process (longer treatment time required), neutralizing the advantage of higher temperatures. Ferric hydroxides precipitate at a lower pH than ferrous iron. In the absence of further complexing substances, because of the low-solubility product of ferric iron hydroxide ($K_S(Fe(OH)_3) \approx 10^{-37}$), precipitation starts at pH 2.5–3.5 depending on the iron concentration, while the ferrous hydroxides precipitate mainly at a pH up to 6. Precipitation, which also depends on temperature, according to Sapieszko [49], is higher and faster as temperature increases from 25°C to 80°C.

But it is important to remark that the design of the solar plant should take it into consideration to (1) avoid solar light concentration, (2) avoid to operate, if possible, during so hot hours in summer or add more Fe if operation is compulsory, (3) recuperate heat from waste water before applying photo-Fenton when the source is too hot, and (4) keep under shadow pipelines and tanks of the solar plant or apply white paint to them. There are so different design decisions related with this statement.

Solar Disinfection and Photocatalytic Disinfection

Solar Disinfection

Outbreaks of disease as a result of the consumption of untreated or improperly treated drinking water contaminated with viral, bacterial, or parasitic agents that cause diarrheal diseases occur on a daily basis worldwide. In developing countries, global death from diarrhea of children aged less than 5 years were estimated at 1.87 million, approximately 19% of total child deaths [50]. The WHO and the United Nations Children's Fund (UNICEF) have recently claimed that improvement of drinking-water quality and basic sanitation are required to decrease childhood morbidity and mortality and to combat the main transmission route of diarrheal diseases (WHO/UNICEF 2007). Chlorine is used extensively, but has the drawback of the disinfection by-products and resistance. Nonchemical disinfection methods are rare in developing countries (UV-C, H_2O_2, and ozone) as energy costs are very high. Recent research attempts to combine sustainability with low cost, leading to an efficient disinfection method not only for drinking water but also for irrigation. One strategy for solving this problem consists of the use of natural sunlight, an abundant source of energy in many developing regions. The bactericidal effect of sunlight has been known for many years. Acra et al. [51] carried out the first practical study of solar disinfection by filling polyethylene bags with water and exposing them to full sunlight and suggested that natural sunlight could destroy pathogenic microorganisms present in the water. Since 1991, the Department of Water and Sanitation in Developing Countries (SANDEC) at the Swiss Federal Institute of Aquatic Science and Technology (EAWAG) has supported the development and application of solar water disinfection, and at present, about one million people worldwide use this system for treating drinking water [52]. Solar water

disinfection (SODIS) is a simple, environmentally sustainable, and inexpensive point-of-use treatment for drinking water, in which contaminated drinking water is placed in transparent plastic polyethylene terephthalate (PET) bottles and exposed to full sunlight for at least 6 h (or 2 consecutive days if there is more than 50% cloud cover) during daylight hours when the maximum intensity of radiation occurs. Sunlight disinfects contaminated water via the action of radiation in the spectrum of UV light and the high temperatures reached in the water. Numerous studies in the last 15 years have demonstrated the effectiveness of simulated and natural SODIS on the inactivation of viruses, bacteria, fungi, and protozoan parasites [18]. At present, SODIS is one of the recommended methods for disinfection of household drinking water [53].

It is widely accepted that solar UV inactivation of microbial cells occurs through a variety of mechanisms depending, inter alia, on the type of UV used for inactivation. Sunlight used during the SODIS process consists mainly of UV-A, and hence, the main inactivation mechanism is a photooxidative process as well as the generation of reactive oxygen species (ROS). ROS [54] include free radicals such as the superoxide anion as well as nonradicals such as hydrogen peroxide. When ROS interacts with DNA, single strand breaks occur as well as nucleic base modifications which may be lethal and mutagenic. Furthermore, oxidation of proteins and membrane damage is also induced. However, many aspects of solar UV-A inactivation are still unclear. Some studies have shown that UV-A damage depends on irradiance and dose [55], defining the first as the power incident per unit area (Wm^{-2}) and the second as the energy reaching a unit area (Jm^{-2}) of the target system during a given exposure time. Other studies indicate the manner in which the dose is delivered (continuously or intermittently) has an effect on the subsequent inactivation observed [56, 57]. Due to a variety of experimental conditions, (the use or non-use of simulation lamps, natural sunlight, volumes and types of water, as well as different organisms) it is very difficult to compare these inactivation results and draw concrete conclusions as to what drives UV-A inactivation. The usual practice of using plastic bottles in SODIS does not allow for a precise determination of the intensity reaching the surface of the bottle mainly because there are a wide variety of bottle geometries and designs in use throughout the developing world. Nevertheless, disinfection efficacy of the SODIS treatment can easily be affected by water turbidity, low irradiation intensity, and regrowth of bacteria after the solar treatment, probably due to photorepair mechanisms [58].

Solar Photocatalytic Disinfection

Solar photocatalytic disinfection with TiO_2 makes use of the reactive hydroxyl radicals produced by the semiconductor surface in contact with the water under irradiation by sunlight. Hydroxyl radical generation takes place in various reaction steps and is accompanied by coreactions depending on the catalyst surface and the molecules in the water, as fully described in section "Solar TiO_2 (Heterogeneous) Photocatalysis Applied to Water Decontamination." Due to the strong reactivity of the radicals, disinfection with TiO_2 was first reported in the 1980s for the Gram-positive bacteria *Lactobacillus acidophilus*, the Gram-negative bacteria *E. coli*, and the yeast *S. cerevisiae* [59].Very recently, the disinfection of water containing the oocysts of the important, very chlorine-resistant pathogen, *C. parvum* [60], and spores of several species of the fungus genus *Fusarium* have been reported at laboratory scale and in distilled water [61]. Although the interaction of the catalyst and the cell wall was neglected in the beginning, recent literature explains the disinfection process by lipid peroxidation of the cell wall followed by lesions on microbial cell walls and leakage of cell content into the media [62]. Probably, in most of these cases, the TiO_2 sticks to the microbial cell wall where the radicals generated produce these lesions, as observed (Fig. 8) in disinfection of *Fusarium* spores with TiO_2 slurry [63]. This disinfection mechanism is only applicable to slurry systems as in immobilized systems particles cannot be absorbed onto pathogen surface.

The configuration of the catalyst in the reactor can significantly affect the disinfection result. Typically, there are two ways to use the TiO_2 for water treatment purposes: (1) as aqueous suspensions of TiO_2 particles, which are usually called *slurry*, and (2) as immobilized TiO_2 over an inert matrix. If the system is designed for drinking-water purification for human consumption,

Solar Detoxification and Disinfection of Water. Figure 8
Inactivation of *Fusarium equiseti* spores (in terms of colony-forming units per milliliter, CFU mL^{-1}) in the presence of water and 35 mg L^{-1} of TiO_2 Degussa P25 in a bottle reactor (200 mL) during a 6-h sunlight exposure

the use of TiO_2 in suspension, as a part of a routine intervention for improving the potability of water at household level (point-of-use water treatment), is not feasible. The photocatalyst particles would have to be removed after solar exposure and before consumption. Unfortunately, in photocatalytic disinfection, almost all immobilized TiO_2 either had very limited yields or involved technical effort leading to high cost. It was even reported that immobilization of TiO_2 produces lower disinfection activity compared to slurry systems [64]. In one of the most important publications on the use of TiO_2 nanoparticles in disinfection, Yu et al. even reported positive results for doping with nonmetals. The authors found that sulfur-doped TiO_2 nanoparticles showed strong visible-light-induced activity that effectively kills *Micrococcus lylae*, a common Gram-positive bacterium, within 1 h on S-doped TiO_2 under visible light irradiation [65].

Comparison of experiments in different seasons, early and later in the day, and under cloudy and sunny conditions, leads one to conclude that solar photocatalytic disinfection does not depend proportionally on solar UV irradiance (solar UV intensity) as long as enough photons have been received for disinfection. The minimum UV energy necessary to reach complete inactivation depends on the microorganism and the reactor configuration. The irradiation mode in the photoreactor has also a high influence on the disinfection behavior. When light exposure is continuous (without temporal interruptions), the bactericidal effect of the process is faster and more efficient than when the light is applied intermittently [66]. Some contributions suggest that this effect can be due to bacterial dark-repair mechanisms which allow bacteria to reactivate after treatment [63]. This fact can also be attributed to the partial damage produced by the radiation which cannot totally inactivate all colonies of bacteria present in the water. It is also known that some damaged cells by UV radiation (not completely died or destroyed) can recover viability by means of DNA repair mechanisms. Rincón and Pulgarin designed the first method of assessing the bactericidal inactivation rate in solar photocatalytic processes for drinking water [56]. They demonstrated that the solar UV dose necessary to reach target disinfection levels cannot be the only indicator of system efficiency and proposed a new parameter called "effective disinfection time" (EDT), defined as the treatment

Solar Detoxification and Disinfection of Water. Figure 9 Photo of a solar disinfection CPC reactor to treat 25 L of drinking water at Plataforma Solar de Almeria facilities

time necessary to avoid bacterial regrowth after 24 h (or 48 h) in the dark after phototreatment.

Vidal et al. [67] published the first pilot plant study about TiO_2 solar photocatalysis for water disinfection. These authors constructed a new low-cost CPC prototype to better use the solar radiation for water disinfection objectives. Very recent work has studied improvement of solar disinfection using supported TiO_2 on resistant flexible materials, like cylinders, pills, balls, mesh, etc. One example is TiO_2 deposited on glass fiber inserted in a tubular photoreactor in a CPC solar collector [68]. Recent research work for concrete applications in the field of solar photocatalytic water treatment has also been sponsored by the European Commission in two different projects. As a final research step, both projects developed solar reactors (Fig. 9) to decontaminate and disinfect small volumes of water [69].

Solar Hardware for Water Decontamination and Disinfection

The specific hardware needed for solar photocatalytic applications has much in common with those used for thermal applications. As a result, both reactors and photocatalytic systems have followed conventional solar thermal collector designs, such as parabolic troughs and nonconcentrating collectors. At this point, their designs begin to diverge, since: (1) the fluid must be exposed to ultraviolet solar radiation, and therefore, the absorber must be UV-transparent, and (2) high temperature does not play a significant role in the photocatalytic process, so no insulation is required.

For many of the solar photocatalytic system components [70], the equipment is identical to that used for other types of water treatment and construction materials are commercially available. Most piping may be made of polyethylene or polypropylene, avoiding the use of metallic or composite materials that could be degraded by the oxidant conditions of the process. All materials used must be inert to degradation by UV solar light in order to be compatible with the minimum required lifetime of the system (10 years). Photocatalytic reactors must transmit UV light efficiently because of the process requirements. With regard to the reflecting/concentrating materials, aluminum is the best option due to its low cost and high reflectivity in the solar UV spectrum on earth surface. The photocatalytic reactor must contain the catalyst and be transparent to UV radiation, providing good mass transfer of the contaminant from the fluid stream to an illuminated photocatalyst surface with minimal pressure drop across the system. Aluminum is the only metal surface that is highly reflective throughout the ultraviolet spectrum. Reflectivities range from 92.3% at 280 nm to 92.5% at 385 nm. Comparable values for silver are 25.2% and 92.8%, respectively. The surfaces currently available that best fit these requirements are (1) electropolished anodized aluminum and (2) organic plastic films with an aluminum coating.

The choice of materials that are both transmissive to UV light and resistant to its destructive effects is limited. Common materials that meet these requirements are fluoropolymers, acrylic polymers, and several types of glass. Quartz has excellent UV transmission as well as good temperature and chemical resistance, but high cost makes it completely unfeasible for photocatalytic applications. Fluoropolymers are a good choice of plastic for photoreactors due to their good UV transmittance, excellent ultraviolet stability, and chemical inertness. One of their greatest disadvantages is that, in order to achieve a desired minimum

pressure rating, the wall thickness of a fluoropolymer tube has to be increased, which in turn will lower its UV transmittance. Acrylics could also potentially be used, but they are very brittle. Other low-cost polymeric materials are significantly more susceptible to be attacked by •OH radicals. Standard glass is not satisfactory because it absorbs part of the UV radiation that reaches it, due to its iron content. Borosilicate glass has good transmissive properties in the solar range with a cutoff of about 285 nm [71]. Therefore, such a low-iron-content glass would seem to be the most adequate.

The original solar photoreactor designs [72] for photochemical applications were based on line-focus parabolic-trough concentrators (PTCs). In part, this was a logical extension of the historical emphasis on trough units for solar thermal applications. Furthermore, PTC technology was relatively mature and existing hardware could be easily modified for photochemical processes. The main disadvantages are that the collectors (1) use only direct radiation, (2) are expensive, and (3) have low optical and quantum efficiencies [73].

One-sun (nonconcentrating) collectors have no moving parts or solar tracking devices. They do not concentrate radiation, so efficiency is not reduced by factors associated with concentration and solar tracking. An extensive effort in the design of small nontracking collectors has resulted in the testing of several different nonconcentrating solar reactors [30, 74]. Although one-sun collector designs possess important advantages, the design of a robust one-sun photoreactor is not trivial, due to the need for weather-resistant and chemically inert ultraviolet-transmitting reactors. In addition, nonconcentrating systems require significantly more photoreactor area than concentrating photoreactors, and, as a consequence, full-scale systems (normally composed of hundreds of square meters of collectors) must be designed to withstand the operating pressures anticipated for fluid circulation through a large field. In uncovered, nonconcentrating systems exposed to the ambient, reactants and catalyst could become contaminated. Very often, the chemical inertness of the materials used (to resist corrosion caused by outdoor operation and exposure to solar irradiation) for constructing the nonconcentrating collector would be difficult to guarantee.

Compound parabolic concentrators (CPCs) are static collectors with a reflective surface that can be designed for any given reactor shape. CPCs were invented in the 1960s [75] to achieve solar concentration with static devices, since they were able to concentrate on the receiver all the radiation that arrives within the collector's "angle of acceptance." They do so illuminating the complete perimeter of the receiver, rather than just the "front" of it, as in conventional flat plates. These concentrating devices have ideal optics, thus maintaining both the advantages of the PTC and static systems. The concentration factor (R_C) of a two-dimensional CPC collector is given by Eq. 24:

$$R_{C,CPC} = \frac{1}{\sin\theta_a} = \frac{A}{2\pi\ r} \tag{24}$$

The normal values for the semiangle of acceptance (θ_a), for photocatalytic applications, are between 60° and 90°. A special case is the one in which $\theta_a = 90°$, whereby $R_C = 1$ (nonconcentrating solar system). When this occurs, all the UV radiation that reaches the aperture area of the CPC (direct and diffuse) can be collected and redirected to the reactor. If the CPC is designed for an acceptance angle of +90° to −90°, all incident solar diffuse radiation can be collected (Fig. 10). The light reflected by the CPC is distributed all around the tubular receiver so that almost the entire circumference of the receiver tube is illuminated and the light incident on the photoreactor is the same that would be impinging on a flat plate [76]. They can make highly efficient use of both direct and diffuse solar radiation, without the need for solar tracking. There is no evaporation of possible volatile compounds, and water does not heat up. They have high optical efficiency, since they make use of almost all the available radiation, and high quantum efficiency, as they do not receive a concentrated flow of photons. Flow also can be easily maintained turbulent inside the tube reactor. Reports exist that provide excellent reviews of the needs toward the solar hardware for photocatalytic processes based on TiO_2 and photo-Fenton application including aspects of optics, geometry, and reactor materials [2, 18, 45, 73]. This literature also reviews the different solar collectors developed up-to-date and pilot-plant and industrial applications.

Future Directions

TiO_2 is a cheap photostable catalyst, and the process may run at ambient temperature and pressure. Additionally, the oxidant, molecular oxygen (O_2), is the mildest. Therefore, in principle, the process involves a mild catalyst working under mild conditions with mild oxidants. However, as concentration and number of contaminants increase, the process becomes more complicated and challenging problems such as slow kinetics, low photoefficiency, and unpredictable mechanisms need to be solved. It is clear that naked TiO_2 needs extra help to undertake practical applications, and this may cause it to lose some of the charm of its mild operation. Therefore, there is a need to find new catalysts able to work with bandgaps which better overlap the solar spectrum, and no "cheap" solution to be used in wastewater treatment has yet been developed.

Photo-Fenton process has the potential of becoming widely applied, especially for wastewaters with medium pollution concentrations (TOC from tens of milligrams per liter up to around 1 g per liter). Several aspects, which in part are currently under development, may also greatly contribute to market introduction upon achieving maturity: (1) catalysts based on immobilized iron; (2) additives which enhance the process performance, regarding either kinetics or pH operation range; (3) optimization of photoreactors, taking into account the processes' specific requirements; and (4) ways to minimize hydrogen peroxide consumption, which is the main cost factor regarding consumables.

Little by little, TiO_2 disinfection research went from basic laboratory studies to the first trials with real disinfection applications. Microorganisms that are very resistant to UV-A irradiation have been successfully inactivated by TiO_2 photocatalysis, and therefore, recent TiO_2 disinfection research focuses more on disinfection applied to more resistant microorganisms.

The irradiation way on the photoreactor has a high influence on the disinfection behavior. When light exposure is made continuously, (without temporal interruptions) the disinfection effect of the process is faster and more efficient than when the light is applied intermittently. The minimum UV energy necessary to reach complete inactivation depends on the microorganism and the reactor configuration. Therefore, there are aspects that are essential to develope a technology, as (1) optimization of photoreactors, taking into account the processes' specific requirements; (2) development of viable process schemes (batch, continuous, semicontinuous); (3) development of process control strategies; (4) study of the influence of process parameters; (5) assessment of the influence of the water chemical parameters; and (6) finding out applications different to potable water disinfection (as a chemical-free system to control pathogens in agriculture).

The current lack of data for comparison of solar photocatalysis with other technologies definitely presents an obstacle toward an industrial application. One issue would be to give sound examples of techno-economic studies. Another aspect should be the assessment of the environmental impact in its broadest sense. One excellent tool is the application of technologies such as life cycle analysis comparing different technologies [77–79]. These studies confirm that solar photocatalysis is a promising technology compared to other investigated technologies, showing the least impact in most of the investigated categories.

Aperture Opening of a solar cavity receiver.

Carnot efficiency Maximum efficiency for converting heat from a high-temperature thermal reservoir at T_H into work in a cyclic process, and rejecting heat to a low-temperature thermal reservoir at T_L, given by $1-T_L/T_H$.

CB (carbon black) Important industrial raw material used as pigment and reinforcement in rubber and plastic products.

CPC (compound parabolic concentrator) Non-imaging concentrating device that is usually positioned in tandem with the primary parabolic concentrating system to further augment the solar concentration ratio.

CSP (concentrating solar power) CSP plants generate electricity by converting solar energy into high-temperature heat using various mirror configurations.

Endothermic Absorbs heat.

Exothermic Rejects heat.

Exergy efficiency (for a solar thermochemical process) The efficiency for converting solar energy into chemical energy, given by the ratio of the maximum work that may be extracted from a solar fuel to the solar energy input for producing such a fuel.

Direct normal solar irradiance Power flux of direct solar irradiation on a surface perpendicular to the sun's rays.

Fuel cell A fuel cell is an electrochemical cell that converts a fuel into electricity. In the presence of an electrolyte, a fuel (e.g., hydrogen) and an oxidant (e.g., oxygen or air) react and generate an electric current.

PEM (polymer electrolyte membrane) fuel cell PEM fuel cells – also called proton exchange membrane fuel cells – deliver high-power density and offer the advantages of low weight and volume, compared with other fuel cells.

Quench Rapid cooling, e.g., of a high-temperature gas mixture to avoid recombination of products.

Solar cavity receiver A well-insulated enclosure, with a small opening to let in concentrated solar energy, which approaches a blackbody absorber in its ability to capture solar energy.

Solar chemical heat pipe Concept for storing and transporting solar energy using a reversible endothermic reaction.

Solar concentration ratio Non-dimensional ratio of the solar flux intensity (e.g., in "suns") achieved after concentration to the normal insolation of incident beam.

Solar fuels Fuels produced with solar energy.

Solar thermochemical process Any endothermic process that uses concentrated solar energy as the source of high-temperature process heat.

Syngas Synthesis gas (a mixture of primarily hydrogen and carbon monoxide), which serves as the building block for a wide variety of synthetic fuels including Fischer-Tropsch type chemicals, hydrogen, ammonia, and methanol.

Definition of the Subject and Its Importance

This entry develops the underlying science of solar-driven thermochemical processes and describes their applications for efficiently producing clean fuels and material commodities.

Introduction

Sunlight is by far the most abundant carbon-neutral energy resource on earth. More energy from the sun strikes the earth's surface in 1 h than is consumed annually by all of the fossil fuels. In fact, using only 0.1% of the earth's land space with solar collectors that operate with a collection efficiency of merely 20%, one could gather more than enough energy to supply the current yearly energy needs of all the citizens of the planet (about $1.3 \cdot 10^{14}$ kWh) [1]. Furthermore, the solar energy reserve is essentially unlimited and its utilization is ecologically benign. However, solar radiation is dilute (only about 1 $kW \cdot m^{-2}$), intermittent (available only during day-time and under clear-sky conditions), and unequally distributed (mostly by the equator). These drawbacks can be overcome by converting solar energy into chemical energy carriers, that is, *Solar Fuels,* that can be long-term stored and long-range transported, from the sunny and desert regions of the earth to the industrialized and populated centers, where much of the energy is needed. Solar fuels can be burnt to generate heat, further processed into electrical or mechanical work, or used directly to generate electricity in fuel cells and batteries, to meet whenever and wherever the customer's energy demands. Solar process heat can also assist in the processing and recycling of energy-intensive materials, thus avoiding greenhouse gas emissions and other pollutants derived from the combustion of fossil fuels for heat and electricity generation.

There are basically three routes that can be used alone or in combination for producing storable and transportable fuels from solar energy [1]: The *electrochemical* route uses solar electricity made from photovoltaic or concentrating solar thermal systems followed by an electrolytic process; the *photochemical/photobiological* route makes direct use of solar photon energy for photochemical and photobiological processes; the *thermochemical* route uses concentrated solar radiation as the source of high-temperature heat for endothermic thermochemical processes.

The thermochemical route offers some intriguing thermodynamic advantages with direct economic implications. It is this approach that is the subject of this entry; the other two routes are beyond its scope.

Figure 1 illustrates the basic idea of the solar thermochemical route [1]. By concentrating the diluted

Solar Energy in Thermochemical Processing. Figure 1
Energy conversion into solar fuels for transportation and power generation – Concentrated solar radiation is used as the energy source of high-temperature process heat for driving thermochemical reactions toward the production of storable and transportable fuels (Adapted from [1])

sunlight over a small area with the help of parabolic mirrors, and then capturing the radiant energy with the help of suitable receivers and reactors, heat at high temperatures can be obtained for carrying out an *endothermic* chemical transformation and producing storable and transportable fuels. These solar fuels ultimately store solar energy within their chemical bonds. Regardless of the fuel, the higher the temperature of the reaction process, the higher the efficiency of energy conversion. Higher temperatures, however, also lead to greater losses by re-radiation from the solar receiver. The thermodynamic implications of such phenomena are examined in the following section.

Thermodynamics of Solar Thermochemical Conversion

The state-of-the-art technology for large-scale collection and concentration of solar energy is based on three main optical configurations using parabolic-shaped mirror reflectors. These are the trough, tower, and dish systems, shown schematically in Fig. 2 [2]. Trough systems use linear, two-dimensional, parabolic mirrors to focus sunlight onto a tubular receiver positioned along their focal line. Tower systems use a field of heliostats (two-axis tracking parabolic mirrors) that focus the sunrays onto a receiver mounted on top of a centrally located tower. Dish systems use paraboloidal mirrors to focus sunlight on a receiver positioned at their focus. Solar furnaces are concentrating research facilities, in which high-flux solar intensities are usually obtained at a fixed location inside a housed laboratory. The traditional design consists of a sun-tracking, flat heliostat on-axis with a stationary primary paraboloidal concentrator [3]; off-axis configurations have also been designed.

The capability of these collection systems to concentrate solar energy is often expressed in terms of their mean flux concentration ratio $\widetilde{C}$ over a targeted area A

Solar Energy in Thermochemical Processing. Figure 2
Schematic of the three main optical configurations for large-scale collection and concentration of solar energy: Parabolic trough, central receiver (tower system), and parabolic dish (From [2])

at the focal plane, normalized with respect to the incident *direct normal solar irradiance I*:

$$\widetilde{C} = \frac{\dot{Q}_{solar}}{I \cdot A} \tag{1}$$

Here, $\dot{Q}_{solar}$ is the solar radiative power input into the target. $\widetilde{C}$ is often given in units of "suns" when normalized to $I = 1\ \mathrm{kW{\cdot}m^{-2}}$. The *solar concentration ratio* typically obtained at the focal plane varies between 30 and 100 suns for trough systems, 500–2,500 suns for tower systems, and 1,000–10,000 suns for dish systems. Higher concentration ratios imply lower heat losses from smaller receivers and, consequently, higher attainable temperatures at the receiver. To some extent, the flux concentration can be further augmented with the help of a non-imaging secondary concentrator, for example, a *compound parabolic concentrator*, referred to as *CPC*, which is positioned in tandem with the primary concentrating system [4].

The solar concentrating systems have been proven to be technically feasible in large-scale pilot and commercial plants aimed mainly at producing electricity. They make use of a working fluid (typically air, water, synthetic oil, helium, sodium, or molten salt) that is heated by solar energy and then used in traditional steam or gas turbines. As of early 2010, the global stock of commercial CSP plants neared 1 GW capacity, mainly in Spain and the United States [2]. Parabolic troughs account for the largest share of the current CSP market, but competing technologies such as towers are emerging. Some plants incorporate thermal energy storage to guarantee continuous capacity and to expand production time.

Solar thermochemical applications, although not developed as far as solar thermal electricity generation, employ similar solar concentrating technologies, mainly based on the solar tower concept capable of achieving high process temperatures [5]. However, high-temperature thermochemical processes require higher solar concentration than state-of-the-art CSP plants, which has an impact on heliostat field layout and plant operation. An advanced concept is the "beam-down" Cassegrain optical configuration for the tower system that makes use of a hyperboloidal reflector at the top of the tower to redirect sunlight to a receiver located on the ground level [6].

Solar chemical reactors for highly concentrated solar systems usually feature the use of a cavity-receiver type configuration, that is, a well-insulated enclosure with a small opening (the *aperture*) to let in concentrated solar radiation. Because of multiple internal reflections, the fraction of the incoming energy absorbed by the cavity greatly exceeds the simple surface absorptance of the inner walls. The larger the ratio of the characteristic length to the aperture diameter of the cavity, the closer the cavity-receiver approaches a blackbody absorber. Smaller apertures also serve to reduce re-radiation losses. However, they intercept a reduced fraction of the sunlight reflected from the concentrators. Consequently, the optimum aperture size is a compromise between maximizing radiation capture and minimizing radiation losses.

The solar energy absorption efficiency of a solar reactor, $\eta_{absorption}$, is defined as the net rate, at which energy is being absorbed, divided by the solar power coming from the concentrator. At temperatures above

about 1,000 K, the net power absorbed is diminished mostly by radiant losses through the aperture. For a perfectly insulated blackbody cavity-receiver, it is given by

$$\eta_{absorption} = 1 - \frac{\sigma T^4}{I\widetilde{C}} \tag{2}$$

T is the nominal cavity-receiver temperature, and σ the Stefan–Boltzmann constant. The absorbed concentrated solar radiation drives an endothermic chemical reaction. The measure of how well solar energy is converted into chemical energy for a given process is the exergy efficiency, defined as

$$\eta_{exergy} = \frac{-\dot{n}\Delta G|_{T_L}}{\dot{Q}_{solar}} \tag{3}$$

$\dot{Q}_{solar}$ is the solar power input, $\dot{n}$ is the molar flow rate of the products, and ΔG is the maximum possible amount of work (Gibbs free energy change) that may be extracted from the products as they are transformed back to reactants at ambient temperature, $T_L = 298$ K. The second law of thermodynamics is now applied to calculate the theoretical maximum *exergy efficiency* $\eta_{exergy,ideal}$. Since the conversion of solar process heat to chemical energy is limited by both the solar absorption efficiency and the Carnot efficiency, the maximum ideal exergy efficiency is given by [7]

$$\begin{aligned}\eta_{exergy,\,ideal} &= \eta_{absorption} \cdot \eta_{Carnot} \\ &= \left(1 - \frac{\sigma T_H^4}{I\widetilde{C}}\right) \times \left(1 - \frac{T_L}{T_H}\right)\end{aligned} \tag{4}$$

where T_H and T_L are the upper and lower operating temperatures of the equivalent Carnot heat engine. In Fig. 3, $\eta_{exergy,ideal}$ is plotted as a function of T_H for $T_L = 298$ K and for various solar concentration ratios. Because of the Carnot limit, one should try to operate thermochemical processes at the highest upper temperature possible; however, from a heat-transfer perspective, the higher the temperature, the higher the re-radiation losses. The highest temperature an

Solar Energy in Thermochemical Processing. Figure 3

Variation of the ideal exergy efficiency $\eta_{exergy,ideal}$ as a function of the operating temperature T_H, for a blackbody cavity-receiver converting concentrated solar energy into chemical energy. The mean solar flux concentration is the parameter: 1,000. . .40,000. Also plotted are the Carnot efficiency and the locus of the optimum cavity temperature $T_{optimum}$ (Adapted from [1])

ideal *solar cavity-receiver* is capable of achieving, defined as the stagnation temperature $T_{stagnation}$, is calculated by setting $\eta_{exergy,ideal}$ equal to zero, yielding

$$T_{stagnation} = \left(\frac{I\widetilde{C}}{\sigma}\right)^{0.25} \tag{5}$$

At this temperature, energy is being re-radiated as fast as it is absorbed. Stagnation temperatures exceeding 3,000 K are attainable with solar concentration ratios above 5,000 suns. However, an energy-efficient process must run at temperatures that are substantially below $T_{stagnation}$. There is an optimum temperature $T_{optimum}$ for maximum efficiency obtained by setting

$$\frac{\partial \eta_{exergy,\,ideal}}{\partial T} = 0 \tag{6}$$

Assuming a uniform power flux distribution, this relation yields the following implicit equation for $T_{optimum}$ [8]:

$$T_{optimum}^5 - \frac{3}{4} T_L T_{optimum}^4 - T_L \frac{I\widetilde{C}}{4\sigma} = 0 \tag{7}$$

The locus of $T_{optimum}$ is shown in Fig. 3. For example, for a solar concentration ratio of 5,000, the optimum temperature of a solar receiver is 1,500 K, giving a maximum theoretical efficiency of 75%, that is, the portion of solar energy that could – in principle – be converted into the chemical energy of fuels. In practice, however, when considering convection and conduction losses in addition to re-radiation losses, the efficiency will peak at a somewhat lower temperature.

The process modeling described in the following paragraphs establishes a base for evaluating and comparing different *solar thermochemical processes* in terms of their ideal exergy efficiency.

Figure 4 depicts a flow diagram of an ideal cyclic process that leads to a fuel, which uses a solar reactor, a quenching device, and a fuel cell. The complete process is carried out at constant pressure. In practice, pressure drops will occur throughout the system. If one assumes, however, frictionless operating conditions, no pumping work is required. The reactants may be pre-heated in an adiabatic heat exchanger where some portion of the sensible and latent heat of the products is transferred to the reactants; for simplicity, a heat exchanger has been omitted. The reactor is

Solar Energy in Thermochemical Processing. Figure 4 Model flow diagram of an ideal cyclic process for calculating the maximum exergy efficiency of a solar thermochemical process (Adapted from [1])

assumed to be a perfect blackbody cavity-receiver. The reactants enter the solar reactor at T_L and are further heated to the reaction temperature T_H. Chemical equilibrium is assumed inside the reactor. The net power absorbed in the solar reactor should match the enthalpy change per unit time of the reaction,

$$\dot{Q}_{reactor,\,net} = \dot{n}\Delta H\,|_{\,Reactants\,@\,T_L \,\rightarrow\, Products\,@\,T_H} \tag{8}$$

Irreversibility in the solar reactor arises from the non-reversible chemical transformation and re-radiation losses $\dot{Q}_{reradiation}$ to the surroundings at T_L. It is found that

$$Irr_{reactor} = \frac{-\dot{Q}_{solar}}{T_H} + \frac{\dot{Q}_{reradiation}}{T_L} + \dot{n}\Delta S|_{\,Reactants\,@\,T_L \,\rightarrow\, Products\,@\,T_H} \tag{9}$$

Products exit the solar reactor at T_H and are cooled rapidly to T_L. The amount of power lost during quenching is

$$\dot{Q}_{quench} = -\dot{n}\Delta H\,|_{\,Products\,@\,T_H \,\rightarrow\, Products\,@\,T_L} \tag{10}$$

The irreversibility associated with quenching is

$$Irr_{quench} = \frac{\dot{Q}_{quench}}{T_L} + \dot{n}\Delta S|_{Products\ @\ T_H \rightarrow Products\ @\ T_L} \tag{11}$$

Introducing a reversible, ideal fuel cell, in which the products recombine to form the original reactants and thereby generate electrical power, closes the cycle. The maximum amount of work that the products leaving the reactor could produce if they combined at T_L and a total pressure of 1 bar is given by

$$\dot{W}_{FC} = -\dot{n}\Delta G|_{Products\ @\ T_L \rightarrow Reactants\ @\ T_L} \tag{12}$$

This work value is also known as the exergy of the products at ambient temperature T_L. The fuel cell operates isothermally; the amount of heat rejected to the surroundings is

$$\dot{Q}_{FC} = -T_L \cdot \dot{n}\Delta S|_{Products\ @\ T_L \rightarrow Reactants\ @\ T_L} \tag{13}$$

The exergy system efficiency of the closed cycle is then calculated using (Eq. 3) as

$$\eta_{exergy} = \frac{\dot{W}_{FC}}{\dot{Q}_{solar}} \tag{14}$$

This thermodynamic analysis can be verified by performing an energy balance and by evaluating the maximum achievable efficiency (Carnot efficiency) from the total available work and from the total power input. The energy balance should satisfy

$$\dot{W}_{FC} = \dot{Q}_{solar} - (\dot{Q}_{reradiation} + \dot{Q}_{quench} + \dot{Q}_{FC}) \tag{15}$$

The available work is calculated as the sum of the fuel-cell work plus the lost work due to the irreversibility associated with the solar reactor and with quenching. Thus,

$$\eta_{\max} = \frac{\dot{W}_{FC} + T_L \cdot (Irr_{reactor} + Irr_{quench})}{\dot{Q}_{solar}} = 1 - \frac{T_L}{T_H} = \eta_{Carnot} \tag{16}$$

Any solar thermochemical process can be thought of in this manner, and their exergy efficiencies can be compared as one criterion for judging their relative industrial potential. The higher the exergy efficiency, the lower is the required solar collection area for producing a given amount of solar fuel and, consequently, the lower are the costs incurred for the solar concentrating system, which usually correspond to half of the total investments for the entire solar chemical plant. Thus, high exergy efficiency implies favorable competitiveness.

Solar Thermochemical Processes

Solar Production of Fuels

Metals are attractive candidates for storage and transport of solar energy [1]. They may be used to generate either high-temperature heat via combustion or electricity via fuel cells and batteries. Metals can also be used to produce solar fuels, such as H_2 from H_2O via hydrolysis, or synthesis gas (*syngas*) from H_2O and CO_2. The chemical products from any of these power- or fuels-generating processes are metal oxides, which, in turn, need to be recycled.

Solar Production of Metals The conventional extraction of metals from their oxides by carbothermic and electrolytic processes is characterized by its high energy consumption and its concomitant environmental pollution. The extractive metallurgical industry discharges vast amounts of greenhouse gases and other pollutants to the environment, derived mainly from the combustion of fossil fuels for heat and electricity generation. These emissions can be substantially reduced, or even completely eliminated, by using concentrated solar energy as the source of high-temperature process heat.

The thermal dissociation and electrothermal reduction of metal oxides proceed without reducing agent, while the carbothermal reduction of metal oxides uses solid carbon C(s) or gaseous hydrocarbons (e.g., CH_4) as reducing agents. The corresponding overall chemical reactions may be represented as follows:

$$M_xO_y \rightarrow xM + \frac{y}{2}O_2 \tag{17}$$

$$M_xO_y + yC(s) \rightarrow xM + yCO \tag{18}$$

$$M_xO_y + yCH_4 \rightarrow xM + y(2H_2 + CO) \tag{19}$$

Here, M denotes the metal and M_xO_y the corresponding metal oxide. The Gibbs free energy of formation, $\Delta_f G^\circ$, of many stable metallic oxides such as

ZnO, MgO, SiO_2, CaO, Al_2O_3, and TiO_2 are large negative numbers that decrease in magnitude with temperature, while their enthalpy of formation, $\Delta_f H^\circ$, remains relatively independent of temperature. Table 1 lists the approximate temperatures at which the standard Gibbs free energy $\Delta_r G^\circ$ for reactions (17), (18), and (19) equals zero for various metal oxides of interest [9, 10].

Thermal Dissociation of Metal Oxides. The solar thermal dissociation of ZnO is among the most promising metal oxide processes. A kinetic study reported an apparent activation energy of $E_a = 361 \pm 53$ kJ·mol^{-1}, which was experimentally determined from isothermal runs in the range 1,800–2,100 K using a solar-driven thermogravimeter – a setup closely approximating the heat and mass transfer characteristics of solar reactors [11]. The E_a is in agreement with previous values ranging from 310 to 350 kJ·mol^{-1} [12] and comparable to non-solar thermogravimetric [13] and solar non-gravimetric [14] analyses. Kinetic parameters determined in an aerosol flow reactor resulted in a pre-exponential factor three orders of magnitude faster than that in stationary reactors [15, 16]. The product gases Zn(g) and O_2 need to be quenched to avoid recombination, which introduces irreversibility and may be a factor of complexity in large-scale utilization [17]. In particular, the quench efficiency is sensitive to the dilution ratio of zinc and oxygen in an inert gas flow and to the temperature of the surface on which the products are quenched [18]. Maximum exergy efficiencies exceeding 50% are possible for a molar ratio of an inert gas to ZnO(s) less than 1 [12]. The condensation of Zn(g) in the presence of O_2 was studied by fractional crystallization in a temperature-gradient tube furnace. The oxidation of Zn is a heterogeneous process and, in the absence of nucleation sites, Zn(g) and O_2 can coexist in a meta-stable state [13].

Except for the thermal dissociation of ZnO, the required temperature for effecting reaction (17) exceeds 3,000 K (Table 1). At temperatures for which $\Delta_r G^\circ$ is positive, solar process heat alone will not make the reaction proceed; some amount of high-quality energy is required in the form of work. It may be supplied in the form of electrical energy in electrolytic processes or in the form of chemical energy by introducing a reducing agent in thermochemical processes.

Electrothermal Reduction of Metal Oxides. An example of a solar electrothermal reduction process that has been demonstrated experimentally in small-scale reactors is the electrolysis of ZnO(s) [19, 20]. At 1,000 K, up to 30% of the total amount of energy required to produce Zn could be supplied by solar process heat using an electrolytic cell housed in a solar cavity-receiver. ZnO(s) is dissolved into an electrolyte composed of a combination of sodium, aluminum, and/or calcium fluoride with a melting point near the process temperature. This choice prevents excess loss of electrolyte due to evaporation. Electric energy is then supplied to two electrodes immersed in a saturated solution. The previous solar thermal electrolytic research [21, 22] identified workable electrolytes as well as crucible and electrode materials; some initial estimates were made of cell resistances and current densities, which were near those found in the industrial

Solar Energy in Thermochemical Processing. Table 1 Approximate temperatures for which $\Delta_r G^\circ$ of reactions (17), (18), and (19) equals zero (From [9, 10])

Metal oxide	Reaction (17): $\Delta_r G^\circ = 0$ at T ~	Reaction (18): $\Delta_r G^\circ = 0$ at T ~	Reaction (19): $\Delta_r G^\circ = 0$ at T ~
Fe_2O_3[a]	3,050 K	920 K	890 K
Al_2O_3	> 4,000 K	2,320 K	1,770 K
MgO	3,700 K	2,120 K	1,760 K
ZnO	2,340 K	1,220 K	1,110 K
TiO_2[a]	> 4,000 K	2,040 K	1,570 K
SiO_2[a]	4,500 K	1,950 K	1,520 K
CaO	> 4,000 K	2,440 K	1,970 K

[a] Fe_2O_3, TiO_2, and SiO_2 decompose to lower-valence metal oxides before complete dissociation to the metal

Hall–Heroult smelting process; materials for the solar reactor were also identified and shown to be reliable under the severe thermal environment of concentrated solar energy. In contrast to the direct solar thermal reduction of ZnO, the solar thermal electrolytic path produces unmixed Zn(g) and O_2 [23]. High-temperature separation of Zn(g) and O_2 further enables recovery of the sensible and latent heat of the products, for example, 116 $kJ \cdot mol^{-1}$ during Zn condensation [24]. Recently, the ionic conductivity was established for electrolytes that have been shown in previous research to support the electrolysis of ZnO (s) at temperatures exceeding 1,200 K [25].

Solar electrochemistry research in this field has been almost exclusively dedicated to ZnO and H_2O, but the investigation could be extended to the high-temperature electrolysis or quasi-electrolysis of MgO, Al_2O_3, and other interesting candidate materials [20].

Carbothermal Reduction of Metal Oxides. For the thermal decomposition of metal oxides into their elements without the application of electrical work, a chemical reducing agent is necessary to lower the dissociation temperature. Coal (as coke) and natural gas (NG, as methane) are preferred reducing agents in blast-furnace processes because of their availability and relatively low price. In the presence of carbon, the uptake of O_2 by the formation of CO brings about reduction of the oxides at much lower temperatures. While reactions (18) and (19) have favorable free energies above the temperatures indicated in Table 1, a more detailed calculation of the chemical equilibrium composition shows that only the carbothermic reduction of Fe_2O_3, MgO, and ZnO will result in significant free metal formation [26]. The carbides Al_3C_4, CaC_2, SiC, and TiC are thermodynamically stable in an inert atmosphere; the nitrides AlN, Si_3N_4, and TiN are stable in N_2 atmosphere. These valuable high-temperature materials were produced in solar furnaces.

Using NG as reducing agent, (Eq. 19) combines in a single process the reduction of metal oxides with the reforming of NG for the co-production of metals and syngas. Thus, CH_4 is reformed in the absence of catalysts and may be tailored to produce high-quality syngas with a molar ratio of H_2 to CO equal to 2, which is especially suitable for synthesizing methanol, a potential substitute for petrol. Thermal reductions of Fe_3O_4 and ZnO with C(s) and CH_4 to produce Fe, Zn, and syngas have been demonstrated in solar furnaces using fluidized bed and vortex-type reactors [27–32]. These reactions are highly endothermic and proceed to completion at temperatures above about 1,300 K.

Example: Carbothermal reduction of ZnO. Zinc production by solar carbothermic reduction of ZnO offers CO_2 emission reduction by a factor of 5, vis-à-vis the conventional fossil-fuel-based electrolytic or Imperial Smelting processes [33]. Furthermore, the use of solar energy for supplying the enthalpy of the reaction upgrades the calorific value of the initial reactants by 39%.

Two examples of solar chemical reactor concepts for producing Zn by reactions (18) and (19) are shown in Figs. 5 and 6, respectively: the "two-cavity" solar reactor based on the indirect irradiation of ZnO + C(gr) [34, 35], and the "vortex" solar reactor based on the direct irradiation of ZnO + CH_4 [30]. A solar chemical "two-cavity" reactor was scaled up in the framework of the European P&D project *SOLZINC*. Testing of the 300 kW solar chemical reactor at a solar tower research facility at temperatures ranging from 1,300 to 1,500 K yielded up to 50 kg/h of 95%-purity Zn with a solar-to-fuel energy conversion efficiency of 30% [36, 37]. The process can be CO_2-neutral if charcoal is used for reducing ZnO.

Solar Production of H_2/CO from H_2O/CO_2 Splitting and/or Fossil Fuels In the long term, the sustainable and carbon-neutral H_2 and synthesis gas (syngas) production from H_2O and/or CO_2 is a promising route involving endothermic thermochemical processes that make use of concentrated solar radiation as the energy source of high-temperature process heat [24]. Syngas is a precursor to liquid hydrocarbons via Fischer–Tropsch or other catalytic reforming processes that are required to power the transportation sectors. Figure 7 illustrates possible solar thermochemical routes to produce H_2 or syngas from H_2O and/or fossil fuels [38]. Feedstocks include *inorganic* compounds such as H_2O and/or CO_2, and *organic* sources such as coal, biomass, and natural gas (NG). The forms of solar fuels are H_2, syngas (with H_2 and CO as main constituents), and their derivatives such as methanol, dimethyl ether (DME), and synthetic oil.

Electrolysis of H_2O – Solar electricity generated by photovoltaics (PV) or concentrating solar thermal

Solar Energy in Thermochemical Processing. Figure 5
Two-cavity solar reactor concept for the carbothermal reduction of ZnO – The upper cavity (absorber) serves as the solar receiver and radiant emitter. The lower cavity is a well-insulated enclosure containing a ZnO/C packed bed. It serves as the reaction chamber and is subjected to thermal radiation from the upper cavity. With this arrangement, the upper cavity protects the quartz window against particles and condensable gases coming from the reaction chamber. The reactor is specifically designed for beam-down incident radiation, as obtained through a Cassegrain optical configuration that makes use of a hyperbolical reflector at the top of the tower to redirect sunlight to a receiver located on the ground level (From [36])

technology (CSP), and followed by electrolysis of water, can be considered as a benchmark [38]. With current technologies, the overall solar-to-H_2 energy conversion efficiency ranges between 10% and 14%, assuming electrolyzers working at 70% efficiency and solar electricity being produced at 15% (PV) and 20% (CSP) annual efficiency. The electricity demand for electrolysis can be significantly reduced if the electrolysis of water proceeds at higher temperatures (1,000–1,200 K) via solid oxide electrolyzer cells (SOEC) [39]. In this case, concentrated solar energy can be applied to provide both the high-temperature process heat and the electricity needed for the high-temperature electrolysis.

Thermolysis of H_2O – The single-step thermal dissociation of H_2O to H_2 and O_2 is known as water thermolysis. Although conceptually simple, its realization is challenging since it needs a heat source above 2,500 K for achieving a reasonable degree of dissociation, reliable materials to operate at these high temperatures, and an effective technique for separating H_2 and O_2 to avoid an explosive mixture. Among the ideas proposed for separating H_2 from the products are effusion separation [7, 40] and electrolytic separation [20, 41]. Rapid quench by injecting a cold gas, expansion in a nozzle, or submerging a solar-irradiated target in liquid water is simple and workable [42, 43], but the quench introduces a significant drop in the efficiency and produces an explosive gas mixture.

H_2O-Splitting Thermochemical Cycles – Water-splitting thermochemical cycles bypass the separation problem and further allow operation at moderately

Solar Energy in Thermochemical Processing. Figure 6 Schematic of a "vortex" solar chemical reactor concept for the combined ZnO reduction and CH_4 reforming – It consists of a cylindrical cavity that contains a windowed aperture with a CPC to let in concentrated solar energy. Particles of ZnO, conveyed in a flow of CH_4, are continuously injected into the reactor's cavity via a tangential inlet port. Inside the reactor's cavity, the gas-particle stream forms a vortex flow that progresses toward the front following a helical path. The chemical products, Zn vapor and syngas, continuously exit the cavity via a tangential outlet port located at the front of the cavity, behind the aperture. Energy absorbed by the reactants is used to raise their temperature to above about 1,300 K and to drive reaction (19) (Adapted from [1])

high temperatures [1]. Previous studies performed on thermochemical cycles were mostly characterized by using process heat at temperatures below 950°C, which are expected to be available in the future from very-high-temperature nuclear reactors (VHTR). Leading candidates for multi-step thermochemical cycles are the three-step sulfur iodine cycle and the two-step sulfur hybrid cycle (with one electrolysis step), both based on the thermal decomposition of sulfuric acid at 1,120 K in a catalytic receiver reactor or at 1,470 K without catalyzer [44, 45]. In recent years, significant progress has been made in the development of optical systems for large-scale solar concentrators capable of achieving mean solar concentration ratios that exceed 5,000 suns. Such high-radiation fluxes allow temperatures above 1,500 K, which are needed for the more efficient two-step thermochemical cycles using metal oxide redox reactions [46–53]:

First step (solar):

$$M_xO_y \rightarrow xM + \frac{y}{2}O_2 \tag{17}$$

Second step (non-solar):

$$xM + yH_2O \rightarrow M_xO_y + yH_2 \tag{20}$$

Here, M denotes a metal and M_xO_y the corresponding metal oxide. The generic cycle is represented in Fig. 8. The first, *endothermic* step is the solar thermal dissociation of the metal oxide to the metal or the lower-valence metal oxide. The second, non-solar, *exothermic* step is the hydrolysis of the metal to form H_2 and the corresponding metal oxide. The net reaction is $H_2O = H_2 + ½O_2$, but since H_2 and O_2 are formed in different steps, the need for high-temperature gas separation is thereby eliminated. Among the most favorable candidate metal oxide redox pairs for this cycle are Fe_3O_4/FeO [54, 55] and ZnO/Zn [56–58]. In both cases, the minimum temperature requirement for the solar step is 2,000 K, and the products need to be either quenched or separated at high temperatures to prevent their recombination. Quenching introduces irreversibility and may be a factor of complexity in large-scale utilization.

Example: Zn/ZnO Cycle. The two-step cycle based on the Zn/ZnO redox pair is one of the most researched solar water-splitting processes. The first step is the thermal dissociation of ZnO using solar process heat, represented as:

$$ZnO \rightarrow Zn + \frac{1}{2}O_2 \tag{21}$$

The second non-solar step is the exothermal reaction of Zn with H_2O to generate H_2, represented as:

$$Zn + H_2O \rightarrow ZnO + H_2 \tag{22}$$

The resulting ZnO is recycled to the first step to close the material cycle, with net reaction being $H_2O \rightarrow H_2 + ½\ O_2$. The products are delivered in separate steps, thereby eliminating their high temperature separation. Since the steps are decoupled, the production of H_2 can be carried out on demand at convenient sites and independent of solar energy availability [59].

Solar Energy in Thermochemical Processing. Figure 7
Thermochemical routes for solar H_2 and syngas production – Indicated is the chemical source of H_2: H_2O for the solar thermolysis and the solar thermochemical cycles; fossil fuels for the solar cracking, and a combination of fossil fuels and H_2O for the solar reforming and gasification. For the solar decarbonization processes, optional CO_2/C sequestration is considered. All of those routes involve energy consuming (endothermic) reactions that make use of concentrated solar radiation as the energy source of high-temperature process heat (Reproduced from [38])

The second law of thermodynamic analysis – derived in (Eqs. 1–16) – is applied for calculating the theoretical maximum exergy efficiency of the two-step Zn/ZnO cycle [1]. Figure 9 depicts the ideal cyclic process for splitting H_2O. The solar reactor is assumed to be a cavity-receiver operating at 2,000 K. The reactant ZnO(s) enters the solar reactor at 298 K and is further heated to the reaction temperature at 2,000 K. The molar feed rate of ZnO to the solar reactor, $\dot{n}$, is set to 1 mol s^{-1}, and is equal to that of H_2O fed to the hydrolysis reactor. After quenching, the products are assumed to separate naturally (without expending work) into gaseous O_2 and condensed phase Zn. Zinc is sent to the hydrolysis reactor to react exothermally with H_2O and form H_2, according to (Eq. 22).

The heat liberated is assumed lost to the surroundings, as given by:

$$\dot{Q}_{hydrolyzer} = -\dot{n}\Delta H|_{Zn+H_2O\,@\,298\,K \rightarrow ZnO+H_2\,@\,298\,K} \tag{23}$$

Thus, the irreversibility associated with the hydrolyzer is:

$$Irr_{hydrolyzer} = \frac{\dot{Q}_{hydrolyzer}}{298K} + \dot{n}\Delta S|_{Zn+H_2O\,@\,298\,K \rightarrow ZnO+H_2\,@\,298\,K} \tag{24}$$

Introducing an ideal H_2/O_2 fuel cell, in which the products recombine to form H_2O and thereby generate electrical power, closes the cycle. $\dot{W}_{FC}$ and $\dot{Q}_{FC}$ are the work output and the heat rejected, respectively, given by

$$\dot{W}_{FC} = -\eta_{FC}\dot{n}\Delta G|_{H_2+0.5O_2\,@\,298K \rightarrow H_2O\,@\,298K} \tag{25}$$

Solar Energy in Thermochemical Processing. Figure 8
Representation of a two-step water-splitting solar thermochemical cycle using metal oxide redox reactions (Adapted from [1])

$$\dot{Q}_{FC} = -T_L \cdot \dot{n}\Delta S|_{H_2+0.5O_2\ @\ 298K\ \rightarrow\ H_2O\ @\ 298K} \qquad (26)$$

The H_2/O_2 fuel cell efficiency η_{FC} is assumed 100% when based on the maximum work output of H_2 (also known as its exergy). Finally, the exergy efficiency is calculated using (Eq. 14). Table 2 gives the results of the calculation for two values of the solar concentration ratio: 5,000 and 10,000. The estimated solar-to-fuel efficiency of the two-step cycle based on the Zn/ZnO redox pair is in the range of 35–39% without heat recovery (h.r.). Recovery of the heat rejected by the quench ($\dot{Q}_{quench}$) and hydrolyzer ($\dot{Q}_{hydrolyzer}$) to preheat the reactants can boost the efficiency to a theoretical maximum of 58–70%.

Figure 10 shows a solar chemical reactor concept for performing the thermal dissociation of ZnO that features a windowed rotating cavity-receiver lined with ZnO particles that are held by centrifugal force [60]. The reactor has a dynamic feeder that extends and retracts within the cavity, allowing for batch-wise formation of a packed bed of ZnO particles evenly distributed over the entire cavity surface. The absorption of concentrated solar energy by directly irradiated reactants provides efficient radiation heat transfer to the reaction site where the energy is needed, by-passing the limitations imposed by indirect heat transport via heat exchangers. 3D computational fluid dynamics (CFD) was employed to determine the optimal flow configuration for an aerodynamic protection of the quartz window against condensable Zn(g).

A 10-kW reactor prototype was fabricated, consisting of a multilayer cylindrical cavity made of sintered ZnO tiles placed on top of a porous 80% Al_2O_3–20%SiO_2 insulation and reinforced by a 95% Al_2O_3–5%Y_2O_3 ceramic matrix composite, providing mechanical, chemical, and thermal stability and a diffusion barrier for product gases. A quenching unit was incorporated at the exit of the cavity to rapidly decrease temperature by injecting Ar into a water-cooled annular outlet [61]. Experimentation was carried out with the 10-kW reactor subjected to mean concentration of 3,000 suns and peak concentration of 5,880 suns [60]. All reactor components performed well at operating temperatures in the range 1,807–1907 K, measured behind the ZnO tiles. The reactor was operated in a transient ablation mode with semi-continuous feed cycles of ZnO particles, characterized by a rate of heat transfer, predominantly by radiation,

Solar Energy in Thermochemical Processing. Figure 9
Model flow diagram of the two-step water-splitting solar thermochemical Zn/ZnO cycle used for the exergy analysis (Adapted from [1])

to the layer of ZnO particles undergoing endothermic dissociation that proceeded faster than the rate of heat transfer, predominantly by conduction, through the cavity walls. Reactor modeling has enabled a more comprehensive and in-depth understanding of the competing mechanisms and the identification of major sources of energy losses, which lead to optimization and scaling up [62–68].

Tubular aerosol flow reactors were designed for the formation of Zn nanoparticles followed by their in situ reaction with H_2O. They featured three zones for Zn evaporation, steam quenching, and Zn/H_2O reaction, respectively [69–74]. These aerosol flow configurations offered high Zn-to-ZnO conversions over short residence times due to augmented reaction kinetics and heat/mass transfer. However, the reactions primarily occurred heterogeneously outside the aerosol jet flow on surfaces with Zn deposition, making the ZnO recovery, process control, and scale-up problematic [59].

Example: SnO/SnO_2 cycle. Another promising metal oxide cycle is based on SnO/SnO_2. Exergy and energy efficiencies of the cycle are 30% and 36% respectively [75]. Atmospheric and reduced pressure experiments showed that the SnO_2 reduction can be performed efficiently at 1,770 K and the SnO hydrolysis at 820 K. A 1-kW solar reactor prototype was successfully tested for continuous operation [38].

Example: CeO_2/Ce_2O_3 cycle. The feasibility of the two-step cycle based on CeO_2/Ce_2O_3 has been demonstrated using a lab-scale solar reactor at 2,300 K and a fixed bed reactor at 700–900 K, where the water-splitting reaction was completed with fast kinetics [53, 76]. In contrast to the Zn-based system, the ceria remains in solid form throughout [38]. The complete

cycle was demonstrated with a 2-kW cavity-receiver containing porous foam made of ceria [77].

Example: Mixed iron oxide cycle. Other metal oxides such as manganese oxide or cobalt oxide, as well as mixed oxides redox pairs – mainly based on iron – have also been considered [78–81]. For example, a mixed iron oxide cycle was demonstrated at the 100-kW power level using a monolithic dual chamber solar reactor (Fig. 11) [82]. A quasi-continuous H_2 flow is produced by cyclic operation of the two reaction chambers through sequential oxidation and reduction steps at 1,050 K and 1,500 K, respectively.

CO_2-Splitting Thermochemical Cycles. A promising alternative to direct CO_2 sequestration is to decompose CO_2 into CO and O_2 using metal oxide redox reactions and concentrated solar radiation:

First step (solar):

$$M_xO_y \rightarrow xM + \frac{y}{2}O_2 \tag{17}$$

Second step (non-solar):

$$xM + yCO_2 \rightarrow M_xO_y + yCO \tag{27}$$

Solar Energy in Thermochemical Processing. Figure 10
Scheme of the solar reactor configuration for the thermal dissociation of ZnO to Zn and O_2 at above 2,000 K – The concept features a windowed rotating cavity-receiver lined with ZnO particles and exposed to high-flux solar irradiation. With this arrangement, ZnO serves simultaneously the functions of radiant absorber, thermal insulator, and chemical reactant (Adapted from [60])

Solar Energy in Thermochemical Processing. Figure 11
Monolithic dual chamber solar receiver-reactor for continuous H_2 production – The concept features a closed receiver-reactor constructed from ceramic multichanneled monoliths. Cyclic operation of the water-splitting and regeneration steps is established in two reaction chambers. Their individual temperature levels are controlled by focusing and defocusing heliostats (Reproduced from [83])

CO can be used as combustion fuel or further processed to synthetic liquid fuels for transportation. O_2 is needed for the oxy-combustion and gasification technologies. Thermodynamic and thermogravimetric-based kinetic analyses were performed for two-step thermochemical cycles based on the Zn/ZnO and FeO/Fe_3O_4 redox reactions [84, 85].

H_2O/CO_2-Splitting Thermochemical Cycles. Producing synthesis gas (syngas) with concentrated solar energy from co-feeding H_2O and CO_2 – the latter eventually captured from air [86–88] – represents a promising path toward sustainable energy utilization [89, 90]:

First step (solar):

$$M_xO_y \rightarrow xM + \frac{y}{2}O_2 \tag{17}$$

Second step (non-solar):

$$xM + y(H_2O + CO_2) \rightarrow M_xO_y + \frac{y}{2}(2H_2 + 2CO + O_2) \tag{28}$$

A solar reactor that incorporates heat recuperation between the reduction and oxidation steps is being developed [52]. The resulting syngas can either be directly combusted for electricity generation in highly efficient combined Brayton–Rankine cycles [91] or further processed via Fischer–Tropsch to liquid hydrocarbon fuels, such as methanol or gasoline [92]. Figure 12 shows the solar reactor technology applied for splitting CO_2 and H_2O using nonstoichiometric ceria redox reactions [77].

Solar Production of H_2 from Fossil Fuels Short-term to mid-term transition processes to solar H_2 encompass the decarbonization of fossil fuels via solar cracking, reforming, and gasification routes that are being investigated in various P&D projects at the power level of several hundred kilowatts [1, 38]. These routes are shown schematically in Fig. 13.

Some of these processes are practiced at an industrial scale, with the process heat supplied by burning a significant portion of the feedstock. Internal combustion results in the contamination of the gaseous products, while external combustion results in a lower thermal efficiency because of the irreversibility associated with indirect heat transfer. Alternatively, using solar energy for process heat offers a threefold advantage: (1) the discharge of pollutants is avoided; (2) the

Solar Energy in Thermochemical Processing. Figure 12
Schematic of the solar reactor configuration for the two-step solar thermochemical cycle for splitting H_2O and CO_2 via ceria redox reactions. It consists of a cavity-receiver containing a porous monolithic ceria cylinder. Concentrated solar radiation enters through a windowed aperture and impinges on the ceria inner walls. Reacting gases flow radially across the porous ceria, while product gases exit the cavity through an axial outlet port. *Red arrow* indicates ceria reduction (oxygen evolution); *blue arrow* indicates oxidation (fuel production) (From [77])

gaseous products are not contaminated by combustion by-products; and (3) the calorific value of the fuel is upgraded by adding solar energy in an amount equal to the ΔH of the reaction [1].

Solar Cracking. The solar cracking route refers to the thermal decomposition of natural gas (NG) and other hydrocarbons, and can be represented by the simplified net reaction:

$$C_xH_y = xC(gr) + \frac{y}{2}H_2 \tag{29}$$

The process thermally decomposes NG in a high-temperature solar chemical reactor, yielding two valuable products: a H_2-rich gas and a marketable high-value nano-material called "*Carbon Black*" (CB). Thus, both H_2 and CB are produced by renewable energy, resulting in potential CO_2 emission reduction of 14 kg of CO_2 and energy saving of 277 MJ/kg H_2 compared to conventional NG steam reforming and standard CB processing [93]. Other compounds may also be formed, depending on the reaction kinetics and on the presence of impurities in the raw materials. The carbonaceous solid product can either be sequestered without CO_2 release or used as valuable material commodity (CB) under less-severe CO_2 restraints. It can also be applied as reducing agent in metallurgical processes. The H_2-rich gas mixture can be further processed to high-purity H_2 that is not contaminated with oxides of carbon and, thus, can be used in *PEM fuel cells* without inhibiting platinum-made electrodes. From the point of view of carbon sequestration, it is easier to separate, handle, transport, and store solid carbon than gaseous CO_2. Further, while the steam reforming and gasification methods require additional steps for shifting CO and for separating CO_2, the thermal cracking accomplishes the removal and separation

Solar Energy in Thermochemical Processing. Figure 13
Solar thermochemical routes for H_2 production using fossil fuels and H_2O as the chemical source – Solar cracking (*left*), and solar reforming and gasification (*right*) (From [1])

of carbon in a single step. In contrast, the major drawback of the thermal decomposition method is the energy loss associated with the sequestration of carbon. Thus, the solar cracking may be the preferred option for NG and other hydrocarbons with high H_2/C ratio. The exergy efficiency for these routes is defined as the ratio of the work output by the fuel cell to the total thermal energy input by both the solar energy and the heating value of the reactants:

$$\eta_{exergy} = \frac{\dot{W}_{FC}}{\dot{Q}_{solar} + HHV_{\text{reactant}}} \tag{30}$$

Here, $HHV_{reactant}$ is the higher heating value of the fossil fuel being processed, for example, about 890 kJ·mol^{-1} for NG. Assuming a 65%-efficient H_2/O_2 fuel cell, η_{exergy} = 30%. This route offers zero CO_2 emissions as a result of carbon sequestration. However, the energy penalty for completely avoiding CO_2 reaches 30% of the electrical output, vis-à-vis the direct use of NG for fueling a 55%-efficient combined Brayton–Rankine cycle.

An experimental investigation on the thermal decomposition of CH_4 into C and H_2 was carried out using a direct-irradiated 5-kW particle-flow solar chemical reactor tested in a solar furnace in the 1,300–1,600 K range [94]. The reactor features a continuous flow of CH_4 laden with μm-sized carbon particles, confined to a cavity receiver and directly exposed to concentrated solar irradiation. Figure 14 shows a novel indirect-irradiated multi-tubular cavity-type solar reactor. A 10-kW solar reactor prototype was successfully tested in the temperature range of 1,823–2,073 K, reaching 97% CH_4 conversion and 75% H_2 yield [95]. This reactor was scaled up to 50 kW and tested in a large solar furnace.

Solar Reforming. The solar reforming of NG and other hydrocarbons, using either steam or CO_2, has been extensively studied in solar-concentrating research facilities with small-scale solar reactor prototypes. Recently, pilot scale test installations have been commissioned.

Example: Solar steam reforming. The steam-reforming of NG and other hydrocarbons can be represented by the simplified net reaction:

$$C_xH_y + x\text{H}_2\text{O} = \left(\frac{y}{2} + x\right)\text{H}_2 + x\text{CO} \tag{31}$$

This process has been scaled up to power levels of 400 kW and tested at 1,120 K and 8–10 bars in a solar tower facility using a solar volumetric reactor [96], as shown schematically in Fig. 15. A concave quartz

Solar Energy in Thermochemical Processing. Figure 14
Schematic of tubular solar reactor for NG cracking – Reactants (CH_4 in Ar) are indirectly heated inside graphite tubes (From [95])

Solar Energy in Thermochemical Processing. Figure 15
Scheme of a direct-irradiated solar reforming chemical reactor (From [96])

window, mounted at the aperture, minimizes reflection losses and permits operation at high pressures. A CPC is implemented at the aperture. The main component is the reticulate porous ceramics (RPC) absorber made of SiC foams and coated with Rh catalyst. A computer tomography–based methodology was applied to determine the transport properties of fluid flow across porous media [97, 98].

Direct-irradiated reactors have the advantage of providing efficient radiation heat transfer directly to the reaction. Furthermore, under proper conditions, direct irradiation may photochemically enhance the kinetics of the reaction. The major drawback, when working with reducing or inert atmospheres, is the requirement of a transparent window, which is a critical and troublesome component under high-pressure and severe gas environment.

Example: Solar chemical heat pipe. The solar dry-reforming of CH_4 with CO_2 offers a sink for CO_2 and – relative to steam methane reforming – produces a more

desirable ratio of H_2 to CO for feed to a Fischer–Tropsch synthesis process [99]. It can be applied in a closed-loop *solar chemical heat pipe* (Fig. 16). The product of this reversible reaction is syngas that can be stored at ambient temperatures and transported to the site where the energy is needed. By the reverse exothermic reaction, stored solar energy is released in the form of high-temperature heat, which can be used, for example, for generating electricity via a Rankine cycle. The products of this reverse reaction are again recycled to the solar reactor, where the process is repeated.

The dissociation/synthesis of ammonia can also be applied in a chemical heat pipe for storage and transportation of solar energy [100]. The endothermic NH_3 dissociation reaction proceeds catalytically at high pressures of 50–200 bar and at temperatures above 700 K. The reverse synthesis of H_2/N_2 delivers heat to a Rankine cycle. The NH_3 fraction in storage is present largely as a liquid, thus automatic phase separation of NH_3 and H_2/N_2 is provided.

Solar Steam Gasification. The solar steam gasification of coal and other carbonaceous materials to produce high-quality syngas is an attractive industrial process represented by the simplified net stoichiometric reaction:

$$C_xH_yO_z + (x-z)H_2O = \left(\frac{y}{2} + x - z\right)H_2 + xCO \tag{32}$$

Other compounds may also be formed, especially with coal, but some impurities contained in the raw materials are cleaned out prior to the decarbonization process. The principal product is high-quality syngas, the building block for a wide variety of synthetic fuels including Fischer–Tropsch type chemicals, hydrogen, ammonia, and methanol. Its quality is determined mainly by the H_2:CO and CO_2:CO molar ratios.

Feedstock: Petcoke. The solar chemical technology for the steam-gasification of heavy crude oil derivatives, such as solid petroleum coke (petcoke) particles, is being developed with participation of the oil industry. For this process, a 5-kW solar reactor was designed that featured a continuous gas-particle vortex flow confined to a cavity receiver and directly exposed to concentrated solar radiation (Fig. 17) [101]. For the 300-kW pilot reactor, complete reaction extent is predicted for an initial feedstock particle size up to 35 μm at residence times of less than 10 s and peak temperatures of 1818 K, yielding high-quality syngas with a calorific content that has been solar-upgraded by 19% over that of the petcoke gasified [102].

Solar Energy in Thermochemical Processing. Figure 16
Solar chemical heat pipe for storage and transportation of solar energy – High-temperature solar process heat is used to drive the endothermic reversible reaction $A \rightarrow B$. The product B may be long-term stored and long-range transported to the site where the energy is needed. At that site, the exothermic reverse reaction $B \rightarrow A$ is effected and yields high-temperature process heat in an amount equal to the stored solar energy $\Delta H_{A\rightarrow B}$. The chemical product A of the reverse reaction is returned to the solar reactor for reuse (From [1])

Solar Energy in Thermochemical Processing. Figure 17
Vortex solar reactor for the steam-gasification of petcoke – This configuration features a continuous gas-particle vortex flow confined to a cavity receiver and directly exposed to concentrated solar radiation. The reactants are injected as liquid slurry of petcoke particles and water (Adapted from [101])

Feedstock: Coal and carbonaceous wastes. High-temperature solar process heat is applied for upgrading low-grade carbonaceous feedstock to produce high-quality syngas for substituting fossil fuels in a cement kiln. Figure 18 shows a 5-kW solar reactor prototype that operated at temperatures up to 1,500 K, yielding high-quality syngas of typical molar ratios $H_2/CO = 1.5$ and $CO_2/CO = 0.2$, and with a calorific content up to 30% upgraded over that of the input feedstock [103]. Solar-to-chemical energy conversion efficiencies varied between 17% and 29%. Experimental demonstration of the high-temperature solar reactor technology at pilot scale of 250 kW is in progress.

Feedstock: Biomass. Solar thermal energy is applied to biomass gasification in a solar reactor that creates temperatures of more than 1,500 K, gasifying any feedstock within seconds [46, 104, 105]. Because the process is driven by solar thermal energy, combustion of the valuable biomass resource is not required. As shown by experiments, nearly all of the carbon in the biomass can be converted to syngas, stretching the ability of the biomass resource to meet energy demand and improving the overall economics of the process. Given these advantages and demonstrated experimental work, solar thermal gasification of biomass appears to be the most promising pathway to near-term renewable hydrogen production from solar resources. Following successful completion of laboratory and on-sun demonstration systems, a 1-MW solar plant was commissioned to transform wood waste and other forms of biomass into synthesis gas that can be converted into gasoline [106].

Solar Production of H_2 from H_2S An optional source of H_2 is H_2S, a highly toxic industrial product recovered in large quantities in the sweetening of NG and in the removal of organically bound sulfur from petroleum and coal [1]. Current industrial practice uses the Claus process to recover the sulfur from H_2S, but the process wastes H_2 to produce low-grade process heat. A thermodynamic and economic study indicates that the pure solar process has the potential of lowering the disposal costs of H_2S vis-à-vis the conventional Claus process while coproducing H_2 without concomitant CO_2 emissions [107].

Solar Production of Material Commodities

Solar Metals and Metal Oxides, Metallic Carbides and Nitrides The extractive metallurgical industry is a major consumer of process heat and electricity, and as such responsible for about 10% of global anthropogenic

Solar Energy in Thermochemical Processing. Figure 18
Section view of a "two-cavity" packed-bed solar reactor for syngas production from carbonaceous wastes – The two cavities are separated by an emitter plate, with the upper one serving as the radiative absorber and the lower one containing the reacting packed bed that shrinks as the reaction progresses (From [103])

greenhouse gas emissions [1]. A solar thermal process would drastically reduce these emissions.

Example: Solar aluminum processing. Solar processing of aluminum could reduce the CO_2 emissions from 44 to 5 t per ton of aluminum. The temperature required to reduce aluminum ores with carbon is in the range 2,400–2,600 K, that is, at the upper limit for practical process heat addition from a combustion source alone. Preliminary tests performed in a concentrating solar facility suggest two feasible solar thermal routes: (1) at about 2,400 K, a mixture of Al_2O_3, SiO_2, and carbon results in an Al–Si alloy, which can be purified after its production; (2) at above 2,500 K, Al_2O_3 and carbon result in an Al-Al_3C_4 mixture of varying compositions [108]. Thermochemical equilibrium calculations indicate the possibility of significantly lowering the onset temperature of aluminum vapor formation via carbothermal reduction of Al_2O_3 by decreasing the total pressure, enabling its vacuum distillation, while bypassing the formation of undesired byproducts Al_2O, Al_4C_3, and Al-oxycarbides. When the reducing agent is derived from a biomass source, the solar-driven carbothermal reduction is CO_2-neutral. Exploratory experimental runs using a solar reactor were carried out at temperatures in the range 1,300–2,000 K and total pressures in the range 3.5–12 mbar, with reactants Al_2O_3 and bio-charcoal directly exposed to simulated high-flux solar irradiation, yielding up to 19% Al by condensation of product gases, accompanied by the formation of Al_4C_3 and Al_4O_4C within the crucible. Based on the measured CO generation, integrated over the duration of the experimental run, the reaction extent reached 55% at 2,000 K [109].

Example: Solar silicon processing. The solar carbothermal reduction of silica to silicon was examined thermodynamically and demonstrated experimentally at vacuum pressures. Reducing the system pressure favors Si(g) formation, enabling its vacuum distillation.

Experimentation in a solar reactor was performed in the range 1,997–2,263 K at $\sim 3 \cdot 10^{-3}$ bar with mixtures of charcoal and silica directly exposed to radiative flux intensities equivalent to 6500 suns, yielding Si purities ranging from 66.1 wt.% to 79.2 wt.%. The Si purity increased with temperature. Solid characterizations showed SiC and SiO as important reaction intermediaries. When the reducing agent is derived from a biomass source, the solar-driven carbothermal process is CO_2-neutral [110]. An additional energy-intensive refining step is required for obtaining high-purity Si employed in electronic and PV applications. The purification of metallurgical grade silicon (MGS) by extraction of boron and phosphorus was experimentally demonstrated using concentrated solar energy in the temperature range 1,823–1,975 K [111].

Example: Solar zinc processing. As described in section "Solar Production of Metals", Zn can be produced from ZnO by a solar thermal, electrothermal, or carbothermal reduction process. Other examples of solar thermal reduction processes that have been demonstrated in solar furnace exploratory runs are the production of Zn by dissociation of its natural ore willemite (Zn_2SiO_4), the combined ZnO reduction and biomass pyrolysis, and the production of Mg and Fe by carbothermal reduction of their oxides.

Metallic carbides and nitrides can be produced by the solar carbothermic reduction of metal oxides. The reaction is generally given by:

$$M_xO_y + C(gr)\{+N_2\} \rightarrow \{M_{x'}C_{y'}, M_{x''}N_{y''}\} + CO \quad (33)$$

Exploratory experimental studies were conducted in solar furnaces, in which nitrides (AlN, Si_3N_4, TiN, and ZrN) were formed for the systems run in N_2, and carbides (Al_4C_3, CaC_2, SiC, TiC) were formed for the systems run in inert atmosphere [24, 26]. These ceramics are valuable materials for high-temperature applications because of their high hardness, excellent corrosion resistance, high melting points, and low coefficients of thermal expansion. CaC_2 is well known as the feedstock for the production of acetylene. The nitrides and carbides AlN, Fe_3C, and Mn_3C may also be used in cyclic processes as feedstock to produce H_2 and hydrocarbons, or may serve as intermediaries in the production of the metal. The hydrolysis of AlN yields NH_3, the hydrolysis or acidolysis of Fe_3C yields liquid hydrocarbons, and the hydrolysis of the various carbides of manganese yields H_2 and hydrocarbons in different proportions. Thus, reaction (33) may be incorporated in cyclic processes of the type shown in Fig. 19, in which the metal oxides resulting from the hydrolysis are recycled to the solar reactor, and CO from reaction (33) may be shifted to H_2 via the water–gas shift reaction.

Solar Fullerenes and Carbon Nanotubes Fullerenes and carbon nanotubes have become a major field in condensed matter physics and chemistry. However, the large-scale production of these materials with high yield and selectivity is still a crucial problem.

Example: Solar fullerene synthesis. Conventional methods for the synthesis of fullerenes like electric arc discharge and laser ablation fail when the process is being scaled up to higher power levels. The solar vaporization process seems to be more promising using the solar reactor shown in Fig. 20, in which a graphite rod contained under vacuum pressure behind a hemispherical quartz window is directly irradiated with peak solar concentration ratios exceeding 7,000 suns, and the vaporized carbon (at temperatures above 3,300 K) is swept out by Ar, quenched, and collected in a bag filter [112]. The key parameters characterizing this process are the carbon soot mass flow rate and the desired product yield. The former is a function of the target temperature, while the latter is a function of specific reactor variables such as fluid flow pattern, residence time, carbon vapor concentration in the carrier gas, target temperature, and temperature distribution in the cooling zone. Single-walled carbon nanotubes were synthesized in gram quantities with a 50-kW solar reactor [113].

Example: Solar-produced carbon nanotubes and nanofibers. Catalytic filamentous carbon (CFC) can be produced by the solar thermal decomposition of hydrocarbons in the presence of small metal catalyst particles. Solar furnace experiments confirmed that nanotubes can be obtained using Co/MgO catalyst for CO and $CH_4 + H_2$, and nanofibers can be obtained on Ni/Al_2O_3 catalyst for CO, CH_4, $CH_4 + H_2$, and C_4H_{10} [114]. Figure 21 shows a solar chemical reactor used for such experimental runs. It consists of a quartz tube containing a fluidized bed of catalyst and Al_2O_3 grains. A secondary reflector, composed of a 2D-CPC coupled

Solar Energy in Thermochemical Processing. Figure 19
Schematic of a two-step thermochemical process for the production of syngas, hydrogen, hydrocarbons, and ammonia, using metal oxides and solar energy – In the first, endothermic step, the metal oxide is carbothermally reduced to a metal carbide or nitride using solar process heat. Subsequently, the carbide or nitride is reacted with water to produce hydrocarbons or ammonia, and CO is water-gas shifted to syngas, while the metal oxide is recycled to the solar step. *M* denotes metal; M_xO_y metal oxide; $M_{x'}C_{y'}$ metal carbide; and $M_{x''}N_{y''}$ metal nitride (From [1])

Solar Energy in Thermochemical Processing. Figure 20
Scheme of a solar reactor for fullerene synthesis (Source: Processes, Materials, and Solar Energy Laboratory, PROMES-CNRS, France)

to an involute, provides uniform irradiation on the tubular reactor. CFC formed has typically the following properties: surface area 100–170 m^2/g, pore volume 0.4–0.8 cm^3/g, micropore volume 0.004–0.008 cm^3/g, and average pore diameter 10–40 nm.

Solar Lime and Cement The thermal decomposition of calcium carbonate (limestone) to calcium oxide (lime)

$$CaCO_3 \rightarrow CaO + CO_2 \tag{34}$$

Solar Energy in Thermochemical Processing. Figure 21 Schematic of a solar reactor for CFC production (Adapted from [115])

Solar Energy in Thermochemical Processing. Figure 22 Schematic of a direct-irradiated rotary reactor for the solar production of lime (Adapted from [116])

is the main endothermic step in the production of lime and cement at 1,300 K. Substituting concentrated solar energy in place of carbonaceous fuels, as the source of high-temperature process heat, is a means to reduce the dependence on conventional energy resources and to reduce emissions of CO_2 and other pollutants.

Figure 22 shows the solar reactor concept for the solar calcination process [116]. The indirect-heating rotary kiln consists of a tilted cylindrical steel drum lined with ceramic insulation and comprising a multi-tube reaction chamber made from high-temperature-resistant SiC. The kiln works with any conventional external heat source in place of concentrated solar radiation, allowing for continuous operation in case of missing or insufficient solar irradiation. A 10-kW solar reactor prototype has been tested at a solar furnace. It processes 1–5 mm limestone particles, producing high purity lime with a degree of calcination exceeding 98% and any desired reactivity. The reactor efficiency, defined as the enthalpy of the calcination reaction at ambient temperature (3,184 kJ kg^{-1}) divided by the solar energy input, reached 30–35% for solar flux intensities of about 2,000 kW m^{-2} and for quicklime production rates up to 4 kg h^{-1}. The kiln prototype operated reliably for more than 100 h, withstanding thermal shocks that occur in solar high-temperature applications. An economic assessment indicates that the cost of solar lime produced in an industrial solar calcination plant of 20–25 MW solar thermal power input is about 2–3 times the current selling price of conventional lime. The solar production of high-purity lime might be an economically viable path for reducing CO_2 emissions in specific market sectors of the lime industry.

Solar Thermal Recycling of Hazardous Waste Materials Solid waste materials from a wide variety of sources, for example, municipal waste incineration residuals, discharged batteries, dirty scraps, automobile shredded residue, contaminated soil, dusts, sludge, and by-products from the metallurgical industry, contain hazardous compounds that are usually vitrified in a non-leaching slag and finally disposed of at hazardous waste-storage sites. However, limited storage space, increasing storage costs, and environmental regulations have led the need for developing technologies that recycle these toxic materials into useful commodities rather than deposit them in dump sites for an undetermined period of time. Thermal processes are well suited for the treatment of these complex solid waste materials. Waste materials containing carbonaceous compounds can be converted by thermal pyrolysis and gasification into syngas and hydrocarbons that can be further processed into other valuable synthetic

chemicals. Those containing metal oxides may be converted by carbothermal reduction into metals, nitrides, carbides, and other metallic compounds.

The commercial recycling techniques by blast, induction, arc, and plasma furnaces are major consumers of fossil-fuel-based electricity and heat. Concentrated solar energy offers the possibility of converting hazardous solid waste material into valuable commodities for processes in closed and sustainable material cycles. Examples of recycling processes demonstrated in solar furnaces are the processing of electric arc furnace dust (EAFD) using the "two-cavity" reactor depicted in Fig. 23 [117], and the melting of Al scrap using a SiC-lined rotary kiln shown in Fig. 24, which can be tilted for discharging molten metal and slag into moulds [118].

Other applications in the area of solar thermal processing of materials that are being explored include hardening of carbon steel, production of Expanded Natural Graphite (ENG) by exfoliation of graphite

Solar Energy in Thermochemical Processing. Figure 23
Schematic of a "two-cavity" solar chemical reactor concept for the thermal recycling of hazardous waste materials – It features two cavities in series. The inner cavity (absorber) is made of graphite and contains a windowed aperture to let in concentrated solar radiation. A CPC is implemented at the reactor aperture. The outer cavity (reaction chamber) is well insulated and contains the waste material that is subjected to irradiation by the graphite absorber separating the two cavities. With this arrangement, the inner cavity protects the window against particles and condensable gases coming from the reaction chamber. Uniform distribution of continuously fed reactants is achieved by rotating the outer cavity (From [117])

Solar Energy in Thermochemical Processing. Figure 24
Schematic of a solar rotary kiln for aluminum melting (Adapted from [118])

intercalated compounds, synthesis of advanced ceramics, and purification of metallurgical grade silicon for photovoltaic applications.

Life Cycle and Economic Analyses

Environmental Impacts. Solar thermochemical processes use concentrated solar radiation as the main or sole source of high-temperature process heat. A solar thermal plant consists of a central receiver system comprising a heliostat field focusing direct solar radiation on a receiver which is mounted on a tower. The receiver includes a chemical reactor or a heat exchanging device. Land consumption and impacts on local flora and wildlife during the build-up of the heliostat field and other facilities are the main environmental issues of the concentrating solar systems [119]. Other impacts are associated with the construction of the steel-intensive infrastructure for solar energy collection due to mineral and fossil resource consumption as well as discharge of pollutants related to today's steel production technology [120]. Direct CO_2 emissions released by the processes are negligible or significantly lower than those from the current fossil-fuel-based processes [119]. All other possible effects are comparable to the conventional processes or can be prevented by safety measures and equipment which are common practice in the chemical industry.

Economics. Economic assessments indicate that solar thermochemical processes for the production of hydrogen and other solar fuels have the potential of becoming economically competitive vis-à-vis alternative paths for producing solar fuels, such as via electrolysis using solar-generated electricity. These studies further indicate that the heliostat field is responsible for about half of the total investment costs for the entire chemical plant, while the cost of the solar reactor represents 10–15%. However, for a fixed product throughput, the solar reactor's efficiency dictates the size of the heliostat field. Thus, reaching high solar reactor efficiencies and reducing the cost of the heliostats per unit area will have a significant impact on reducing the unit cost of the solar fuel. Application of credits for CO_2 mitigation and pollution avoidance will further enable the solar thermochemical technologies to compete favorably with fossil-fuel-based processes. The weaknesses of these economic evaluations are related primarily to the uncertainties in the viable efficiencies and investment costs of the various components due to their early stage of development and their economy of scale [1].

Future Directions

Solar thermochemical processes have favorable long-term prospects because they avoid or reduce costs for CO_2 mitigation and pollution abatement. The products are renewable fuels and material commodities for delivering clean and sustainable energy services. Further research and development toward optimization and scale-up of the solar thermochemical process and reactor technology is warranted.

The various solar fuels production and materials processing technologies are at diverse stages of maturity. Short-to-mid-term "transition" processes such as solar reforming of NG, solar gasification of carbonaceous materials, or solar carbothermal reduction of ZnO are expected to be ready for large-scale industrial implementation by 2015–2020. The long-term thermochemical cycles for splitting H_2O and CO_2, such as the ZnO/Zn cycle, the mixed iron oxide cycle, the iodine-sulfur cycle, and others, will require further fundamental research and prototype reactor development. Their large-scale industrial implementation is predicted for 2020–2025, provided the price of fuel will account for the external costs of greenhouse gas mitigation and pollution abatement.

Nomenclature

A	Area of reactor aperture (m^2)
$\widetilde{C}$	Mean solar flux concentration ratio (−)
HHV	Higher heating value of a fuel
I	Direct normal solar irradiance ($kW \cdot m^{-2}$)
Irr_{quench}	Irreversibility associated with quenching ($kW \cdot K^{-1}$)
$Irr_{reactor}$	Irreversibility associated with solar reactor ($kW \cdot K^{-1}$)
$Irr_{hydrolyzer}$	Irreversibility associated with hydrolyzer ($kW \cdot K^{-1}$)
$\dot{n}$	Molar flow rate ($mol \cdot s^{-1}$)
$\dot{Q}_{FC}$	Rate of heat rejected to surroundings from fuel cell (kW)
$\dot{Q}_{hydrolyzer}$	Rate of heat rejected to surroundings from hydrolyzer (kW)
$\dot{Q}_{quench}$	Rate of heat rejected to surroundings from the quench (kW)
$\dot{Q}_{reactor,net}$	Net power absorbed by solar reactor (kW)
$\dot{Q}_{reradiation}$	Re-radiated power from solar reactor (kW)
$\dot{Q}_{solar}$	Solar power input to solar reactor (kW)
T	Temperature (K)
T_H	High reservoir temperature (K)
T_L	Low reservoir temperature (K)
$T_{optimum}$	Optimum temperature of solar cavity receiver for maximum η_{exergy} (K)
$T_{stagnation}$	Maximum temperature of a blackbody absorber (K)
$\dot{W}_{FC}$	Rate of maximum theoretical work from fuel cell (kW)
ΔG	Gibbs free energy change ($kJ \cdot mol^{-1}$)
ΔH	Enthalpy change ($kJ \cdot mol^{-1}$)
ΔS	Entropy change ($kJ \cdot mol^{-1} \cdot K^{-1}$)
$\eta_{absorption}$	Solar energy absorption efficiency (−)
η_{Carnot}	Carnot efficiency (−)
η_{exergy}	Exergy efficiency of the thermochemical cycle (−)
η_{FC}	Efficiency of H_2/O_2 fuel cell (−)
σ	Stefan-Boltzmann constant ($5.6705 \cdot 10^{-8}$ $W \cdot m^{-2} \cdot K^{-4}$)

Albedo The albedo is a unitless measure of the reflectivity of an object. Albedo is defined as the ratio of reflected to incident electromagnetic radiation. Here, albedo is related to the reflection of solar irradiance.

Earth's orbit The path of the Earth around the Sun.

Earth's revolution The movement of the Earth around the Sun.

Equinox The days when daylight hours and night hours are equal, halfway between summer and winter.

Hadley circulation Large-scale equatorial circulation of air, driven by gradients in surface and air heating caused by surface irradiance. The Hadley circulation is characterized by rising motion near the equator, poleward horizontal flow of the arisen air at an altitude of 10–15 km, with a subsequent descending motion in the subtropics. The descended air flows then in turn back to the equator near to the surface. The Hadley circulation is closely related to the trade winds, tropical rainbelts, subtropical deserts, and jet streams.

Insolation Solar irradiance is also called insolation.

Inter tropical convergence zone The ITCZ appears as a belt of clouds encircling the globe close to the equator. It is the region where the trade winds originating in the Northern and Southern hemispheres come together.

Luminosity The amount of electromagnetic energy a body radiates per unit of time.

Solar irradiance The quantity of the incoming sun "rays" or, in other words, the amount of electromagnetic power per area. The direct irradiance is the part which comes from the direction of the Sun without scattering. The diffuse direction is the irradiance which comes from all directions.

Stratosphere The atmospheric layer above the troposphere.

Summer solstice The day when the altitude of the Sun is the greatest, close to the first day of summer.

Teleconnection Teleconnection in atmospheric science refers to climate anomalies or anomalies on the flow regime being related to each other at large distances (typically thousands of kilometers).

Top of atmosphere The top of atmosphere (TOA) is approximately 100 km above the Earth's surface. It is the border between the Earth's atmosphere and

space. The number density of the particles decreases logarithmic Al with increasing altitude. At a certain point (TOA) the density is close to zero, the atmosphere ends and space begins.

Troposphere The atmosphere of the Earth is divided into different layers. The layer near to the surface is called the troposphere. The altitude of this layer varies but is typically around 10 km. Above the troposphere the stratospheric layer begins. The transition between troposphere and stratosphere is called stratopause.

Winter solstice When the Northern hemisphere has the fewest daylight hours.

Definition

Solar irradiance is a driving factor of life on Earth and the Earth's energy budget. It is the driving factor also for wind and solar energy and thus guarantees the energy supply in a world running out of fossil energy. The distribution of land surface and vegetation types as well as the different climate regions of the world is predominantly a result of the ratio between the amount of solar surface irradiance and precipitation. For example, a large amount of solar surface irradiance combined with a lack of precipitation leads to decertification. Hence, the distribution of solar irradiance plays a dominant role for the diversity and distribution of plants, animals, and cultures.

Solar irradiance leads to energy uptake by the ocean and land surfaces and a subsequent warming of these surfaces. It is also a key quantity for evaporation. The energy cycle of absorbed solar irradiance, evaporation, emitted heat, and transport drives weather and climate. The distribution of solar irradiance is therefore key to the energy and water cycle of the Earth and hence the weather and climate system.

Solar irradiance affects also the well-being of humans. Large amounts of solar irradiance could easily lead to heat stress, sun burning, and the need for large local noon siestas, while low amounts during a period of several months increases the danger of depression, sometimes called the seasonal affective disorder (SAD).

The above-mentioned interactions of solar surface irradiance distribution with the distribution of animals, plants, climate zones, and weather regimes, demonstrate that the distribution of solar irradiance is important for life on Earth and for the development, establishment, and modifications of cultures. Solar irradiance distribution is the driving factor for wind circulation systems. Further on, knowledge of the solar irradiance distribution is needed for infrastructure planning of solar energy. The distribution of solar irradiance will be the dominant factor for the distribution of solar energy systems.

Introduction

The solar irradiance at the top of atmosphere (TOA) and at the Earth's surface is a key parameter for climate monitoring and analysis. It plays a dominant role in the energy fluxes between the surface and the atmosphere. Solar irradiance is a forcing quantity for heat fluxes, which compensates negative or positive values of the Earth's radiation budget, forcing atmospheric motions.

Solar surface irradiance with a large geographical coverage and a high resolution in space-time are necessary for a better understanding of climate variability and climate dynamics (extremes) and for assessing the radiative forcing of the climate system. Moreover, these data are quite well suitable for the verification of regional climate model output or reanalysis data respectively (e.g., [1]). Finally, irradiance went into climate indices, which are of value for monitoring and seasonal prediction of specific climate impacts (e.g., [2]).

Beside its importance for climate, the solar surface irradiance is also necessary for an efficient planning and monitoring of solar energy systems. Furthermore, it is of importance for the satellite-based estimation of drought and evaporation. Solar surface irradiance assessment from geostationary satellites constitutes a powerful alternative to meteorological ground networks for climatological data [3] and is the primary source of information in regions where ground-based measurements are sparse (e.g., Ocean, Africa). The top of atmosphere irradiance can only be observed from satellites. Knowledge about the global distribution and its temporal variation is quite important for all the above-mentioned applications and research fields.

The Sun and the Earth

The Sun emits a nearly constant flux of energy in the form of electromagnetic waves. The average total energy per unit time is called the solar luminosity and has a value of about $3.839*10^{26}$ W [4]. The solar luminosity is related to the solar irradiance, which is defined

as the electromagnetic energy per unit area and time or power per unit area. In physical terms the solar irradiance is defined as the flux density. The flux density of solar irradiance decreases with increasing distance from the Sun in the power of $1/r^2$. The irradiance (flux density) at the top of atmosphere at a distance of 149.5 million kilometers from the sun is approximately I_0 = 1,366 W/m^2 (see article of Gueymard for further details). I_0 is sometimes called the solar constant, but this term is somehow misleading, since the solar irradiance at the top of atmosphere is by no means constant. There are significant variations in the solar irradiance at the top of atmosphere due to variations in the sun activity (luminosity) and in the distance of the Earth relative to the Sun. The variation of the sun activity affects the solar emission and so the solar irradiance. The changes in solar irradiance due to variations in sun activity are usually within the range of 2–3 W/m^2. The variation in the distance between the Sun and the Earth arises from the orbit of the Earth around the Sun. It is not a circle, which would mean equal distance throughout the year, but an ellipse, see Fig. 1. It takes the Earth one year to make one revolution around the Sun on an elliptical orbit (1). As a consequence, the Earth-Sun distance varies sinusoidally throughout the year in the order of ±1.7%. This leads to a small variation of the solar irradiance. Often a distance factor f, varying between 1.03 and 0.97, is used to account for the seasonal variations in the solar "constant" within models. Along the Earth's elliptical orbit around the Sun, the Earth performs a complete rotation around its tilted spinning axis each day (Fig. 1, red line). One rotation takes 24 h and is responsible for the daily cycles of day and night and the change of the solar altitude throughout the day.

Both the distance between the Earth and the Sun as well as the sun activity affects the whole globe and not only parts of it. It is therefore obvious that both phenomena do not affect the distribution of solar irradiance and are therefore not discussed in more detail in this entry.

Global Distribution of the Top of Atmosphere Irradiance

There are two effects that define the global distribution of the solar irradiance at the top of atmosphere (TOA): the spherical shape of the Earth and the tilt of the Earth's rotation axis relative to the Sun. The Earth's rotation axis is currently tilted at 23.5° with respect to the ecliptic axis, the line drawn from the center of the Earth perpendicular to the ecliptic plane (Fig. 1). This tilt is called the obliquity of the Earth's axis.

The Earth has a spherical shape; hence, close to the equator the incoming solar irradiance covers a smaller region than at higher latitudes. Here, the same amount of incoming solar irradiance is spread over a larger region; hence the solar irradiance is lower per unit area. In mathematical terms, this effect is expressed by the cosine of the solar zenith angle (SZA). The solar zenith angle equals 90° minus the solar altitude of the Sun above the horizon, as illustrated in Fig. 2. The effect of the spherical shape of the Earth leads to a latitude dependency of the solar zenith angles (solar altitudes), as illustrated in Fig. 3. The higher the latitude the lower the highest possible solar altitude, hence, the lower the solar irradiance. (The effect of the solar altitude on the solar irradiance (both at TOA and surface) is by far larger than that of the Sun-Earth distance, as it modifies the solar irradiance in the range between 0 and 1,366. If the solar zenith angle is 60°, the irradiance is only half the value at 0°.) The maximum possible solar irradiance is not at the equator throughout the year, but moves up and down within +/−23.5 degrees latitude as a consequence of the Earth's obliquity (the tilted rotation axis of the Earth). This leads to a seasonal variation of the solar irradiance and hence the global solar irradiance patterns. This effect is illustrated in Fig. 4. The maximum solar altitude at each latitude is therefore dependent on the date of the year. The highest possible solar altitude at local noon at the equinoxes around March 20 and September 23 is 90° minus the local latitude. The highest possible solar altitude (local noon of the day) at the local latitude varies with ±23.5° throughout the year (Fig. 5, left). In the Northern hemisphere it is +23.5° around June 21 and −23.5° around December 21; in the Southern hemisphere this is reversed. This in turn leads to seasonal variations in the maximum and mean solar irradiance. The local noon solar irradiance (maximal possible value during any day) at a given latitude is given by Eq. 1 for every longitude and date.

$$I_{max} = I_0 * cos(latitude + \omega_t) \quad (1)$$

Solar Irradiance, Global Distribution. Figure 1
Illustration of the Earth's orbit around the Sun leading to a seasonal change of distance between the Sun and the Earth. The Sun is not positioned exactly in the center of the ellipse (cross of *gray lines*); rather it lies in one of the two focal points of the ellipse. Once a year (at so-called Perihelion), the Earth is closest to the Sun. At present, the Earth will be closest to the Sun on January 3. At that time the solar irradiance at the top of the atmosphere (TOA) is about 1,415 W/m^2. Six months later, the Sun-Earth distance reaches a maximum (so-called Aphelion). The solar irradiance during Aphelion is only about 1,322 W/m^2 at TOA. Thus, the solar irradiance has a pronounced seasonal cycle, which has a range of about 93 W/m^2 or $\pm$3.3% of the solar constant. The date for Perihelion and Aphelion is slightly changing throughout the decades

whereby ω_t varies between $\pm 23.5°$ throughout the year. Figure 5 (right) provides the distribution of the TOA solar irradiance at local noon, calculated with Eq. 1 for a fixed solar constant. The tilt of the Earth's rotation axis leads also to a seasonal increase or decrease in daylight hours – the farther away from the equator, the greater the effect. Moving from the equator to the north the number of daylight hours decreases with increasing latitude during the northern winter. For each degree change of latitude there is a reduction in daylight hours and a commensurate increase in the hours of darkness. North of the so-called polar circle the Sun does not rise above the horizon during winter time. (Of course from the equator to the South it is the same.) Daylight hours and SZA can be calculated by the use of the so-called equation of time for every date and location [5]; daylight hours can be also calculated online, e.g., at http://www.jgiesen.de/daylight.

The amount of daylight hours does significantly affect the global distribution of solar irradiance at the top of atmosphere. The maximum solar irradiance is reached at a latitude of $\sim 25°$ in each hemisphere, but due to the amount of daylight hours, the solar irradiance does not decrease with increasing latitude but remains constant at this level during the respective summer solstice period. This is illustrated in Fig. 6.

The number of daylight hours together with the maximum available solar altitude defines the distribution of solar irradiance at the top of atmosphere. Both effects are in turn a result of the Earth's rotation around a tilted axis together with the Earth's orbit around the Sun.

Solar Irradiance, Global Distribution. Figure 2
Illustration of the definition of solar altitude and solar zenith angle

It is important to note that the driving factor for summer and winter is the tilt of the Earth and not the distance between the Earth and the Sun.

Figure 7 shows the mean solar irradiance at the top of atmosphere averaged over 25 years. The seasonal effect of the rotation-axis tilt is compensated and the distribution is symmetric around the equator. Figure 8 illustrates the seasonal effect of the tilt on the solar irradiance at the top of the atmosphere. For individual months or seasons, the distribution is not symmetric around the equator, but leads to low irradiance values in either the southern or northern part of the Earth, especially toward the poles. The data illustrated here is from the NASA/GEWEX surface radiation budget project [6]. The Global Energy and Water-cycle Experiment (GEWEX) is an integrated program of research, observations, and science activities with the goal of providing data sets to support global and regional climate monitoring and analysis. The NASA/GEWEX SRB project is a major component of the GEWEX experiment. The objective of this project is to determine solar and thermal flux densities at the top of atmosphere and at the surface with the precision

Solar Irradiance, Global Distribution. Figure 3
Illustration of the effect of the spherical shape of the Earth, which leads to different solar zenith angles (solar altitude) in different regions of the world. The higher the latitude the lower the highest possible solar altitude, hence, the lower the solar irradiance

Solar Irradiance, Global Distribution. Figure 4
Illustration of the effect of the Earth's tilt on the global solar irradiance distribution. In spring and autumn the solar irradiance distribution is centered around the equator, but in summer and winter it is not

Solar Irradiance, Global Distribution. Figure 5
The *left* figure illustrates the effect of the tilted rotation axis on the seasonal variation of the solar altitude which in turn affects the seasonal variation of the solar irradiance. The seasonal variation of the local noon solar irradiance at the top of atmosphere is illustrated in the *right* figure. It is important to note that the shape and amount of the latitudinal solar irradiance distribution is significantly modified by the increase or decrease of daylight hours resulting from the Earth's rotation around the tilted spinning axis

Solar Irradiance, Global Distribution. Figure 6

It is important to note that the shape and amount of the latitudinal solar irradiance distribution is significantly modified by the increase or decrease of daylight hours resulting from the Earth's rotation around the tilted spinning axis. Night hours reduce the amount of available irradiance. The number of night hours varies for a given site throughout the year. The further away from the equator the greater the difference between the maximum and minimum amount of night hours. The *left* figure demonstrates the effect on the latitudinal distribution for December and the *right* for June. The maximum solar irradiance is still reached close to a latitude of 23.5° but remains constant at this level for increasing latitudes in the respective summer season (December in the southern hemisphere and June in the northern hemisphere). The pattern of the latitudinal solar irradiance distribution at the equinoxes is almost not affected, as the tilt of the earth does not affect the relation between daylight and night hours at equinox

Solar Irradiance, Global Distribution. Figure 7

An 25-year average of monthly mean solar irradiance at the top of atmosphere. The annual mean is symmetric around the equator (Data source: Surface Radiation Budget Project http://gewex-srb.larc.nasa.gov/. Figure generated with NASA NCAR web plotting tool http://mynasadata.larc.nasa.gov/las/servlets/dataset)

Solar Irradiance, Global Distribution. Figure 8
Distribution of solar irradiance at the top of atmosphere in W/m for August (*left*) and February (*right*). The figures illustrate the seasonal change of the solar irradiance at the top of atmosphere (Data source: Surface Radiation Budget Project http://gewex-srb.larc.nasa.gov/. Figure generated with NASA NCAR web plotting tool http://mynasadata.larc.nasa.gov/las/servlets/dataset)

needed to monitor and analyze climate variations and decadal-to-centennial climate trends. More details are available at http://gewex-srb.larc.nasa.gov/. The data is available and can be visualized with the web service provided by http://mynasadata.larc.nasa.gov/las/servlets/dataset. This tool has been also used for the visualization of all SRB plots within this document.

Role of Satellites

The top of atmosphere albedo (ratio upwelling and downwelling irradiance) is an essential climate variable. The incoming irradiance and outgoing radiation at the top of atmosphere can only be observed continually by satellites. Satellite sensors observe the radiation reflected by the Earth. The observed radiation has to be converted to flux densities in order to derive the top of atmosphere albedo. The radiation observed by satellite sensors can also be used to derive the solar surface irradiance. The law of energy conservation provides the basis for the satellite-based retrieval of solar surface irradiance. Solar irradiance cannot get lost, it is either reflected or absorbed by the atmosphere or it reaches the surface. The absorption effect of the atmosphere is well defined by radiative transfer; the satellite-observed reflections allow, therefore, the estimation of solar surface irradiance.

The radiation reflected by the Earth can be monitored by instruments with a broadband channel or by multispectral instruments, which observe the radiation in several different solar and thermal regions. Satellites have significantly increased the knowledge of the Earth's radiation budget and the distribution of solar irradiance at the top of atmosphere and the surface. In contrast to ground-based observations, space-borne observations have the advantage of a large geographical coverage (geostationary satellites) up to global coverage (polar orbiting satellites such as ERBE and CERES). This is especially important for direct irradiance since the network of ground-based measurements is very sparse.

Different satellites with calibrated broadband radiometers on board have been operated during the last decades. Typical examples for polar orbiting satellites are the Earth Radiation Budget (ERB) sensors aboard Nimbus-7 [7], the Earth Radiation Budget Experiment (ERBE) sensors [8] and the Clouds and the Earth's Radiant Energy System (CERES) [9]. On geostationary satellites, the Geostationary Earth Radiation Budget (GERB) sensor on-board of the Meteosat Second Generation satellites [10]. The multispectral sensors on both polar orbiting and geostationary satellites are also used to produce surface radiation products, as well as top of atmosphere albedo. Examples are the Spinning Enhanced Visible and Infrared Imager (SEVIRI) radiometers onboard the METEOSAT Second Generation (MSG) satellites [11], Geostationary Operational Environmental Satellites (GOES) ([12] and references therein), and Moderate Resolution Imaging Spectroradiometer (MODIS) [13].

Global Distribution of Surface Irradiance

Effect of Atmosphere

Solar surface irradiance is radiation from the Sun received on a given surface area, and its unit is usually Watts per square meter W/m^2. The solar surface irradiance results from the solar irradiance at the top of atmosphere (TOA). Without atmosphere, the solar irradiance at the top of atmosphere (TOA) and at the surface would be identical. The atmosphere affects the amount and distribution of the solar surface irradiance by scattering and absorption, as illustrated in Fig. 9.

Solar Irradiance, Global Distribution. Figure 9 Illustration of the scattering and absorption effects. Scattering changes the direction of the incoming solar irradiance and leads therefore to an attenuation of the incoming irradiance, as parts of the irradiance are scattered back to space. Parts of the radiation are also scattered forward and reach the Earth surface. In addition, scattering leads to a longer optical path length through the Earth's atmosphere and hence to an increased absorption

This leads to a significant mismatch between the distribution of the solar irradiance at the surface and at the top of atmosphere.

At the top of atmosphere all solar radiation is in the form of direct irradiance. This means that all incoming irradiance is received from the direction of the Sun. Constituents of the atmosphere lead to scattering and absorption of solar radiation. Scattering adds a significant diffuse component to the incoming solar irradiance. Diffuse irradiance is predominantly uniformly distributed over the sky sphere and originates from all directions.

Irradiance consists of electromagnetic waves. These waves have the ability to force oscillations (and electronic transitions) within air molecules. The energy of the wave is reduced as part of the energy is "absorbed" by energy transfer to "vibrational" energy, which in turn leads to attenuation of irradiance. The respective process is called absorption. The higher the "particle" density along the optical path of the irradiance the higher the attenuation by absorption.

The magnitude of irradiance attenuation induced by the atmospheric components due to absorption or scattering is generally expressed in terms of optical depth.

$$I = I_o \cdot exp(\tau) \tag{2}$$

Here I_0 is the incoming irradiance, τ is the optical depth resulting from absorption or scattering and I is the direct irradiance reaching the ground. Optical depth is always defined for a vertical column. The attenuation due to absorption/scattering increases with increasing optical path through the atmosphere given by an increase of the solar zenith angle. For a slant column, Eq. 2 transforms into:

$$I = I_0 * exp\left(\frac{\tau}{cos(sza)}\right) \tag{3}$$

here, *sza* is the solar zenith angle. The term $\frac{\tau}{cos(sza)}$ is called the optical thickness of the respective quantity.

The sum of diffuse and direct irradiance is called global irradiance (which refers to the integration over the sphere) or solar surface irradiance. Global distribution of global irradiance sounds a bit confusing; hence, we prefer here to use the term "solar surface irradiance." The relevant atmospheric scattering and absorption processes comply Rayleigh scattering on air molecules, absorption by air molecules, absorption by water vapor and ozone, the absorption and scattering by aerosols, and cloud water droplets or cloud ice particles, respectively. The effect of cloud absorption is in general quite low relative to the scattering effect [14]. These processes are described in more detail in other articles of this book (e.g., Gueymard); here, their role in the spatial distribution of solar irradiance is discussed. Both absorption and scattering lead to an attenuation of the incoming solar irradiance. The magnitude of attenuation depends on the amount of the respective atmospheric components, hence, the optical depth of the atmospheric components. Consequently, atmospheric components which are not uniformly mixed but show specific spatial patterns affect the distribution of solar irradiance at the surface, leading to a significant mismatch with the distribution at the top of atmosphere. However, well-mixed (uniformly distributed) atmospheric components do not affect the distribution of solar irradiance on the Earth's surface, and would only copy and paste the distribution given at the top of atmosphere to the surface. For example, air molecules in the atmosphere scatters the solar irradiance, the respective process is called Rayleigh scattering. Air molecules are (horizontally) well mixed and uniformly distributed; hence they do not have specific spatial patterns and do not affect the global distribution of solar surface irradiance. However, Rayleigh scattering affects the amount and the spectral distribution of the incoming solar irradiance, leading to blue sky (Rayleigh scattering decreases in the power of 4 with increasing wavelength, hence blue light is much more scattered than the rest of the visible light. As significant parts of the blue light "is scattered" out of the white light, the sky is illuminated by blue light). Also stratospheric aerosols (above $\tilde{1}0$ km) are in general (horizontally) well mixed and do not affect the distribution of solar surface irradiance (with exceptions of fresh large volcanic eruptions). Ozone shows large spatial patterns on a global scale but the effect on the broadband solar irradiance is quite small as the absorption takes place in the UV. Deviations of 100 DU correspond to a change of 5 W/m, which is in the range of the uncertainty of solar irradiance measurements. Thus, the effect of ozone on the spatial distribution of irradiance is rather small.

While air molecules are well mixed and show a homogeneous distribution, this is not the case for clouds, water vapor, and tropospheric aerosols. They are not uniformly distributed, but show specific spatial distribution patterns with large spatial gradients (inhomogeneous spatial distribution). Hence, the magnitude of attenuation resulting from these components differs in different regions of the world as well as on the smaller local scales. Consequently, they affect the global distribution of the irradiance at the Earth surface leading to specific spatial and seasonal patterns. The solar irradiance distribution is dominated by clouds on a global scale. However, especially for direct irradiance, the effect of the spatial aerosol distribution is also quite important. This outlines that the distribution of the surface solar irradiance depends significantly on the distribution of the above-mentioned atmospheric parameters and is not only defined by top of atmosphere distribution.

Figure 10 shows the effect of the atmosphere on the solar surface irradiance in relation to the top of

Solar Irradiance, Global Distribution. Figure 10
Effect of the atmosphere on the solar surface irradiance in relation to the top of atmosphere irradiance. The monthly mean solar irradiance at TOA (*top*) and at the earth surface (*bottom*) is quite different due to atmospheric attenuation (Data source: Surface Radiation Budget Project http://gewex-srb.larc.nasa.gov/. Figure generated with NASA NCAR web plotting tool http://mynasadata.larc.nasa.gov/las/servlets/dataset)

atmosphere distribution. The constant amounts of solar irradiance along the latitudes given at TOA are not apparent at the surface due to the effect of atmospheric attenuation dominated by clouds. Significant gradients in the solar irradiance do also occur along latitudes.

Direct irradiance is much more sensitive to aerosols and clouds than solar surface irradiance. This is a result of scattering induced by these variables. Scattering of irradiance leads to an attenuation of the direct irradiance and in turn "generates" diffuse radiation. Parts of the diffuse radiation are scattered back to space, but parts reach the ground and add to the solar surface irradiance. Diffuse irradiance reaching the ground is lost for direct irradiance but counts to the (overall) solar surface irradiance, hence solar surface irradiance is less sensitive to scattering induced by clouds and aerosols.

Therefore direct irradiance is much more affected by the global distribution of clouds and aerosols than solar surface irradiance. In contrast, direct irradiance shows no significant higher sensitivity regarding water vapor and ozone absorption. Water vapor and ozone are pure absorbers, do not scatter, and are therefore not a source for diffuse radiation. The remaining slight differences in the sensitivity between direct and (overall) solar surface irradiance are due to the different optical path length through the atmosphere. Direct irradiance takes per definition always the shortest way through the atmosphere. Diffuse radiation reaching the surface is affected by a longer optical path through the atmosphere due to multi-scattering, leading to increased absorption.

Figures 11 and 12 illustrate the larger effect of clouds and aerosols on direct irradiance comparatively to (overall) solar surface irradiance, respectively.

Figure 12 shows the effect of aerosol optical depth on the direct irradiance in comparison to the (overall) solar surface irradiance.

Direct Irradiance and Direct Normal Irradiance

Solar irradiance is usually discussed with reference to horizontal planes. This is motivated by the close relation of solar surface irradiance with the energy uptake of the Earth's surface. For example, for climate applications the solar irradiance on the Earth's surface is of main concern. Therefore, the solar irradiance is usually given on a horizontal plane in order to provide the energy per square meter surface and not for a surface tilted toward the Sun.

However, for solar energy systems, the irradiance on a plane (surface) tilted toward the Sun is of main concern. The direct irradiance received by a surface tilted toward the direction of the irradiance is called direct normalized irradiance (DNI), because the surface is always normal to the direction of the Sun. Conversely, "direct irradiance" usually refers to a horizontal plane (e.g., the ocean surface). Next, the differences between the direct irradiance and DNI are briefly discussed.

Figure 13 shows the difference between direct irradiance and DNI for a diurnal cycle and a standard atmosphere. It is evident that DNI is much higher than direct irradiance for systems with a surface directed toward the Sun, leading in turn to a much higher energy potential.

The pure geometrical effect of the solar zenith angle on solar irradiance discussed and illustrated in Fig. 3 is compensated by the tilt of the (moving) surface receiving the direct irradiance.

Of course, DNI is in the same relative way affected by clouds and aerosols as the direct irradiance. The global distributions of direct horizontal irradiance and DNI are therefore similar, although DNI values are always larger. A surface which is always normal to the direction of the Sun (e.g., by use of a tracking system) collects the maximum possible direct irradiance throughout the year. This reduces the effect of lower solar altitudes at higher latitudes. The magnitude of the seasonal (winter-summer) variation in DNI is significantly reduced compared to that of direct irradiance due to a reduced dependency of DNI on the solar zenith angle effect. However, the amount of annual daylight hours in combination with the increase of air mass (AM) at higher latitudes still lead to large latitudinal gradients in annual means of DNI and seasonal variations of DNI induced by the Earth-Sun geometry discussed in section "The Sun and the Earth".

The global distribution of DNI and direct irradiance is similar but not identical. This has to be considered for the following discussion of direct irradiance.

Effect and Distribution of Clouds, Water Vapor, and Aerosols

Clouds *Clouds* consist of particles (water and ice droplets) that predominantly scatter the incident radiation (Mie-Scattering). Only a small amount of solar

Solar Irradiance, Global Distribution. Figure 11
Solar surface irradiance (*left*) and direct irradiance (*middle*) for an instantaneous satellite overpass in June 2006. The effect of clouds is much higher for direct irradiance, as can be seen by the increase of the *blue* colored area (identical color range). On the *right*, the effect of cloud albedo on the irradiance is illustrated (Data source: CM-SAF, www.cmsaf.eu)

Solar Irradiance, Global Distribution. Figure 12

Effect of aerosol optical depth on the global and direct solar surface irradiance for a fixed water vapor content of 15 mm, a single scattering albedo of 0.8 (urban aerosol) and an air mass of 2 and 1, corresponding to a solar zenith angle of 0° and 60°

Solar Irradiance, Global Distribution. Figure 13

Left: The difference between the direct irradiance on a horizontal plane and on a tilted plane normal to the direction toward the Sun (Direct Normalized Irradiance). For typical AOD background value of 0.2, the effect is quite large, especially for SZA above 30°. However, for higher aerosol load, here 0.8 a typical value for polluted areas or biomass burning regions, the effect is significantly smaller in absolute terms. *Right*: Illustration of the DNI effect. *Bottom*, short link to the importance of this effect for solar thermal power plants

radiation is absorbed by clouds. The ratio between the incident and reflected radiation is called cloud albedo. The cloud albedo depends on the size and amount of water or ice droplets constituting the cloud. For water clouds, this is usually specified by the liquid water content (or Cloud Optical Depth) and the effective radii of the water droplets.

Clouds show specific spatial and temporal distribution patterns in different scales, affecting significantly the distribution of solar irradiance. It is well known that huge regional differences in cloudiness do exist, even though clouds appear rather chaotic sometimes. For example, the Sahara desert has a permanent low cloud cover throughout the year, while Northern England is almost permanently covered by clouds during winter time.

Figure 14 shows the long-term spatial distribution of clouds and their effect on direct irradiance. It is evident that clouds strongly impact the direct irradiance in regions close to the equator, where tropical (humid) conditions prevail. These regions would otherwise have outstanding conditions for solar energy. It is remarkable that due to high cloudiness, regions at higher latitude such as Southern Europe (Spain, Italy, Turkey) provide a higher solar energy potential than "cloudy" regions close to the equator. The Sahara has a high potential for solar energy since it is predominantly cloud free. However, in Western Sahara, lower values of direct irradiance are apparent, because high aerosol loads strongly affect direct irradiance. The effect of aerosols on direct irradiance is discussed in more detail later on. Next, the cloud distribution and its effect are discussed.

Operational cloud observations are usually made at synoptical weather stations and by meteorological satellites. Cloud information can be well retrieved from satellites due to the large reflection signal. Estimates based on these observations result in a global mean cloud cover of around 60–70% [15–17]. However, there is a huge regional diversity in the overall cloud coverage and cloud optical depth. Both quantities define the magnitude of the cloud albedo and hence of the reflection of irradiance due to the presence of clouds. Dominant drivers for the global cloud cover distribution are large-scale circulation systems and the spatial distribution of moisture. The Hadley

Solar Irradiance, Global Distribution. Figure 14

A 23-year mean of effective cloud albedo (*left*) and direct irradiance at the surface (*right*). Regions of large cloudiness are associated with low direct irradiance and vice versa. The spatial distribution of clouds is reflected in the direct irradiance at the surface. Although the effect of clouds is more pronounced for direct irradiance it constitutes the most important effect for the spatial distribution of solar surface irradiance (global irradiance), too (Data source: CM-SAF, www.cmsaf.eu)

circulation, an essential circulation system, is the generator of the Inter-Tropical Convergence Zone (ITCZ). At the ITCZ humid air is forced upward. As a consequence, optical thick clouds are formed quite regularly, leading to a relatively low solar irradiance. Consequently, the equatorial tropics exhibit a maximum of cloud cover of more than 65%.

The ITCZ is not always located at the same latitudes, but moves up and down. The magnitude of the movement differs for different regions around the equator. Moreover, the ITCZ has different widths around the world. The up and down movement (dynamics) of the ITCZ leads to a large seasonal change in solar irradiance, especially in Africa and surrounding oceans. However, over the eastern Pacific Ocean and over the Atlantic Ocean in the Northern hemisphere, the ITCZ remains nearly permanently over the same latitudes. This is due to the fact that the temperatures of the sea surface in the Atlantic in the Southern hemisphere are nearly always relatively low just south of the equator. This is also the case in the eastern Pacific Ocean [18, 19].

On both sides of the ITCZ, strong meridional gradients in cloud cover are apparent over the oceans, with large cloud cover on the eastern side of the large ocean basins and relative minima further west. This is caused by the existing large gradients in sea surface temperature. In contrast, the subtropical land areas contain the absolute minima in cloud cover over the desert regions of the planet. Here, the humidity needed to generate clouds is not available from the surface and the drying effect of the subsiding motion leads to the most arid regions in the world. The discussion so far demonstrates the extreme effect of the ITCZ on the distribution of clouds and hence on solar irradiance. It is one of the main drivers of solar surface irradiance distribution in the tropics and subtropics.

An additional feature affecting the global distribution of solar irradiance is the presence of very cloudy areas over certain subtropical ocean regions. Examples are the coastal waters close to the coastlines of Peru, California, and also close to Namibia, as illustrated in Fig. 15.

All these regions are characterized by cold ocean water and hence low sea surface temperatures. As a consequence, a relatively stable and very humid boundary layer forms in these areas, which is almost always linked to a relative thick layer of clouds.

Solar Irradiance, Global Distribution. Figure 15
A 11-year average of monthly mean cloud albedo, derived with the MAGICSOL method [20]. The cloud albedo indicates the amount of solar irradiance that is reflected back to space. The effect of the ITCZ (*yellow*/*green* regions around the equator) and increased cloud albedo close to Namibia is "clearly" apparent (Data source: CM-SAF, www.cmsaf.eu)

The extratropical oceans are the regions of maximum cloud cover across the globe. In these regions a mean cloud cover in excess of 80% is observed. Different types of clouds such as those produced in and around mid-latitude cyclones [21], and low-level stratus clouds which have a high optical thickness, contribute to this large overall coverage with clouds [22]. The maximum cloud cover over land in extratropical regions can be found over North-West Europe where the absence of large north-south-oriented mountain ranges allows clouds and humidity to penetrate well inland, forced by eastward-moving low-pressure systems. Over the rest of the extratropical continental, the cloud cover is typically around 50%.

The distribution of clouds has to be taken carefully into account for the planning of solar power plants due to their quite large effect on direct irradiance. Even relative small regional trends in the mean cloudiness could lead to a large decrease in the solar energy resource.

Hence, for an accurate estimation of the energy yield of solar power plants, accurate information

about the (effective) cloud albedo or cloud fraction and cloud optical depth is needed.

Water vapor (absorption) affects the global distribution of solar irradiance. Water vapor only absorbs and does not scatter solar radiation. The distribution depends on the amount of evaporation and the subsequent transport of water vapor by wind systems. The attenuation effect of water vapor is much smaller than that of clouds. Clouds consist of water droplets or ice droplets, hence of water vapor in liquid or solid phase. Thus, high values of water vapor are often correlated with high cloudiness. In contrast to aerosols, water vapor is available with appropriate accuracy by reanalysis data. It constitutes therefore not a major challenge for an accurate estimation of solar irradiance distribution.

Also tropospheric aerosols are irregularly distributed and affect significantly the global distribution of solar surface irradiance, particularly that of direct irradiance. Aerosols absorb and scatter irradiance. The relation between scattering and absorption depends on the aerosol type and, hence, the composition of the aerosols. This relation can be expressed by the single scattering albedo. A single scattering albedo of 1 means that the aerosols only scatter. A single scattering albedo of 0.8 means that the attenuation of the irradiance resulting from the aerosols is to 80% due to scattering and to 20% due to absorption. Soot is a typical component which leads to "urban" aerosol types with relative high absorption, whereas irradiance is mainly scattered by maritime nonpolluted aerosols. Direct irradiance is only affected by the aerosol optical depth (AOD). However, the spectral distribution of the AOD depends on the aerosol type. This has to be considered if AOD values measured at certain wavelength are used within solar irradiance prediction models.

The distribution of aerosols is predominantly a result of three different sources in combination with their subsequent transport by wind systems. The main sources leading to high aerosol load are:

- Burning of fossils. This leads to hot spots in the aerosol distribution around large cities or industry regions. The aerosols are characterized by a high soot portion.
- Biomass burning. Regions with regular biomass burning events exists, e.g., in Africa and South America. Biomass burning leads to significant increase of aerosol load.
- Desert aerosols and dust outbreaks due to desert storms, which are naturally linked to large desert regions. Desert aerosols are usually larger relative to other aerosol types and have therefore a significantly different spectral effect.

A low aerosol load is usually common over oceans (see article of Gueymard for details). The predominant aerosol type is called maritime aerosol and is characterized by a low aerosol optical depth in combination with a low amount of soot. Naturally, this aerosol type contains a significant amount of sea salt. Over oceanic areas close to significant sources of dust outbreaks (desert storms), biomass burning, or industrial regions, high aerosol loads may regularly occur. Depending on the direction and strength of the wind systems, aerosols are transported away from the original source and high aerosol load can be found far away from the coastlines.

Solar energy systems are predominantly of interest in regions of low cloudiness, hence in regions with high frequency of cloud-free sky. The aerosol distribution is therefore quite important for solar energy systems, particularly those using concentrators, even though clouds dominate the global distribution of solar irradiance. High aerosol loads, e.g., due to biomass burning, desert storms, or industrial pollution, can significantly decrease the solar irradiance in regions with low cloudiness, hence with, otherwise, high potential for solar energy. As power plants are expected to play a significant role in the future energy system, accurate knowledge of aerosol information is needed for appropriate energy predictions. This outlines the importance of accurate aerosol information for the planning of solar energy systems. Within this framework, it is remarkable that there is a huge regional diversity in the overall aerosol load and optical depth data provided by the existing data sources [23] and [24].

Figure 16 shows the global distribution of aerosol optical depth and its extreme effect on the direct normal irradiance (DNI) for clear sky conditions and a solar zenith angle of 60°. The illustrated aerosol optical depth is the median of the values provided by Chemical Transport Models participating in the AeroCom project [23]. Of course, the depleting effect

Solar Irradiance, Global Distribution. Figure 16
Aerosol optical depth (*left*) and direct normal irradiance (*right*) for March and August, using the aerosol climatology based on median values of the AeroCom project [23]. The DNI is given for an air mass of 2 (solar zenith angle of 60) throughout the globe. It illustrates the effect of aerosols on DNI for identical SZA, but is not representative for monthly means. Especially in regions with high aerosol load, the attenuation induced by aerosols reduces the direct irradiance extremely. Also evident, the large variation in the distribution illustrated here by the differences between March and August (Data source: Data derived with gnu-MAGIC)

of aerosols is only a fraction of the cloud effect in many regions of the world, but not in regions with low cloudiness, where accurate knowledge of the aerosol optical depth becomes very important. Moreover, the differences between March and August illustrate the large seasonal variation in the aerosol distribution and the subsequent effect on DNI.

In regions with large aerosol loads, specific patterns in the global distribution of DNI become apparent. Hence, accurate estimation of energy yield of solar power plants requires accurate information about the aerosol optical depth. Unfortunately, aerosol information is currently known only with a relative high uncertainty. Figure 17 provides the difference between the predicted DNI using an aerosol climatology based on AeroCom median values [23] and that using the GADS/OPAC climatology [25]. The latter is well established but somehow outdated aerosol climatology. The large differences obtained over some regions illustrate the need for accurate aerosol information for the planning of solar power plants. The effect of uncertainties in aerosol information on DNI will be discussed in more detail in section 5.5

Land Surface Snow can increase the diffuse irradiance and hence the solar surface irradiance, especially under cloudy conditions. For polar regions, this means that the distribution of irradiance is also affected by ocean/snow patterns. This leads to quite high values of solar surface irradiance for the snow-covered Greenland relative to the surrounding ocean, as shown in Fig. 10. Additionally, the low difference in the

Solar Irradiance, Global Distribution. Figure 17
Difference in DNI for March and August and an AM of 2. The difference in DNI arises from the use of two different aerosol climatologies, AeroCom based on one hand and GADS/OPAC on the other. The differences are quite large, demonstrating the importance of accurate aerosol information (Data source: Image derived with gnu-MAGIC, http://sourceforge.net/projects/gnu-magic)

brightness between clouds and snow (ice) as seen from satellites increases extremely the uncertainty in the estimation of cloud parameters and in turn also that of satellite-based solar irradiance.

Discussion of Surface Irradiance Distribution

The spatial and temporal distribution of the solar irradiance at the surface is a result of the top of atmosphere distribution and its changes due to the atmospheric attenuation induced by clouds, aerosols and water vapor. The distribution of solar irradiance at the top of atmosphere shows the highest values in regions close to the equator. However, the effects of clouds, aerosols, and water vapor significantly alter the distribution at the surface. This in turn has significant consequences for the global distribution of the solar irradiance, e.g., relative low solar irradiance observed in the equatorial belt.

The spatial and temporal variations in the distribution of the atmospheric variables (clouds, aerosols, water vapor) are driven by atmospheric physics and dynamics and the resulting circulation systems of wind and humidity. This leads to specific distributions and typical periodic variations of cloudiness, water vapor content, and aerosol load, resulting in specific solar surface irradiance variations on different spatial and temporal scales.

Some important processes are briefly discussed in the following. The Hadley circulation [19] is a main driver of atmospheric dynamics and affects significantly the solar distribution in the "equatorial belt." The equatorial tropics are dominated by the ascending branch of the Hadley circulation. The ascent of wet air leads to cooling and ultimately to areas with very high cloudiness known as the Intertropical Convergence Zone (ITCZ). The seasonal variation of solar irradiance at the top of the atmosphere is a driver for the up and down "movement" of the Hadley circulation from the north to the south of the equator. This movement (dynamics) leads to a large seasonal change in solar irradiance, especially over Central Africa and the surrounding oceans. However, over the Eastern Pacific Ocean and over the Atlantic Ocean, the ITCZ remains in the northern hemisphere nearly permanently [19] and [18]. The Hadley circulation, generating the ITCZ, is very important for the solar irradiance distribution as it occurs in a region with maximum solar irradiance at the top of atmosphere and, hence, in regions with a theoretically high solar resource. In the ITCZ, high

water vapor content and cloudiness strongly attenuate solar radiation. As a consequence, the solar surface irradiance in the equatorial belt is lower than at higher latitudes, although solar irradiance at the top of atmosphere is maximal. This mismatch illustrates the effect of atmospheric variables on solar irradiance. Moreover, the seasonal variation of the top of atmosphere irradiance is rather small in the equatorial belt, whereas seasonal variations of the ITCZ lead to large seasonal variations in the available solar surface irradiance.

Figure 18 shows the distribution of solar irradiance over Africa, as affected by the ITCZ.

Similarly Fig. 19 shows the spatial distribution of the mean solar surface irradiance (based on a 25-year average).

As a consequence of the ITCZ, the maximum solar surface irradiance over land surfaces is located in a subtropical belt between ca. 15°–35°N/S and not in the equatorial belt. Around 80% of the solar surface irradiance there is available as direct irradiance as a consequence of low cloudiness. Many of the developing nations in northern Africa and southern parts of Asia lie within this "sun" belt and have therefore optimal conditions for the use of solar energy. The solar resource is in particular extremely high in the tropical and subtropical deserts of the Earth, due to high sun angles and a low frequency of cloudiness. However, missing infrastructure together with heavy dust storms is a big handicap for the use of solar energy in these regions.

In the descending branches of the Hadley circulation on both sides of the ITCZ, strong meridional gradients in solar irradiance are apparent over the oceans, with relatively low solar irradiance on the eastern side of the large ocean basins and relative maxima further west.

In the belts close to mid-latitudes (35°–45°), the solar irradiance is significantly decreased because of the lower solar altitudes given at higher latitudes. In addition, cloudiness and atmospheric pollution are important factors that decrease the solar surface irradiance in many regions.

Large cloud amounts in storm tracks in combination with low solar irradiance at TOA account for the much lower values over mid-latitudes, especially outside the respective summer seasons. In addition, numerous cyclones generate a relatively persistent cloud cover.

In general regions beyond 45°–50° North or South have quite low amounts of solar irradiance and therefore less favorable conditions for the use of solar energy.

Solar Irradiance, Global Distribution. Figure 18
Long-term annual mean solar irradiance for Africa. Solar surface irradiance (*left*) and direct irradiance (*right*) (Data source: www.cmsaf.eu)

Solar Irradiance, Global Distribution. Figure 19

A 25-year average of monthly mean solar surface irradiance (global irradiance). The effect of atmospheric attenuation is clearly visible in comparison with Fig. 7 (Data source: Surface Radiation Budget Project http://gewex-srb.larc.nasa.gov/. Figure generated with NASA/NCAR web plotting tool http://mynasadata.larc.nasa.gov/las/servlets/dataset)

Solar surface irradiance decreases to a minimum near the poles because of low sun angles and the fact that the Sun does not rise above the horizon during long periods of the year, even though the daily solar irradiance may be high during summertime.

Atmospheric oscillations also contribute to the spatial and temporal distribution of solar irradiance, e.g., ENSO, the El Nino-Southern Oscillation. ENSO episodes are among the most important interannual phenomena occurring in the climate system. The eastward advance of connective activity from the warm pool region to the central and eastern equatorial Pacific and the increase of high thick clouds over those regions are associated with a large decrease in solar irradiance. Hence, ENSO largely affects the solar distribution and also leads to anomalies in the spatial patterns of solar irradiance at the surface [26].

One of the most prominent oscillations (teleconnection pattern) in the northern hemisphere is the North Atlantic Oscillation (NAO) [27]. The NAO combines parts of the East Atlantic and West Atlantic patterns originally identified for the Northern hemisphere winter season by Wallace et al. [28]. The NAO is associated with basin-wide changes in the intensity and location of the North Atlantic jet stream and storm tracks and in large-scale modulations of the normal patterns of zonal and meridional heat and moisture transport [29]. These effects in turn result in changes of cloudiness.

The distribution of atmospheric variables and the resulting attenuation of solar radiation is by no means constant throughout the year as a result of the discussed circulation (oscillation) systems. This results in typical seasonal distribution patterns of solar surface irradiance. Figure 20 shows the seasonal variation of solar surface irradiance and direct irradiance for the Meteosat click. Figure 21 shows the mean solar surface irradiance distribution for two specific months as an example.

Trends in the circulation system, e.g., an increase of the intensity of the Hadley circulation, can significantly affect the solar resource and therefore need to be considered seriously.

On a regional scale, the decrease of water vapor and aerosols with altitude leads to a concomitant increase in clear-sky solar irradiance. In contrast, "mountains" are often associated with an increased cloudiness relative to the surroundings, which leads to a decrease in solar irradiance. These orographic clouds develop in

Solar Irradiance, Global Distribution. Figure 20
Seasonal long-term means of solar irradiance for the Meteosat disk. The spatial distribution of direct horizontal irradiance (SID) and solar surface irradiance (SIS, also called global irradiance) is similar on a larger scale. However, in general much lower amounts of direct irradiance are present and on a smaller spatial scale significant differences occur (Data source: CM-SAF, www.cmsaf.eu. Figure generated by R. Posselt, MeteoSwiss)

response to the forced lifting of air caused by the Earth's topography. The subsequent cooling leads to the generation of clouds. The attenuation effect of orographic clouds is usually only partially compensated by the increase in clear sky irradiance. This effect is also present over low mountain ranges and can be additionally forced by temperature differences between sea and land surfaces at coastlines. This in turn leads to specific regional patterns in mean values of solar irradiance, which have to be considered within the planning of solar energy systems, an example is given in Fig. 22.

Even though clouds dominate the distribution of atmospheric attenuation on a global scale, special attention has to be paid to the aerosol effect in regions with low cloud frequency in connection with solar energy applications. Figure 23 illustrates the effect of water vapor and aerosols on the distribution of solar irradiance in the absence of clouds.

Accuracy and Uncertainty of Solar Irradiance

Currently, different solar irradiance data sets are available for solar energy applications. Some of them are available free of charge via a web user interface. Satellite-derived and reanalysis data sets usually cover the whole globe. This indicated the main problem for solar energy prediction is not to locate sources of data, but to get accurate data or at least reliable accuracy information about the data. It is essential that the accuracy of the data is well defined in order to evaluate the applicability of the data and to provide information about the uncertainty of energy predictions to potential users. However, appropriate measures of accuracy are often missing and the performance indicators are often misleading. For example, in many publications and validation reports dealing with gridded solar irradiance data, the mean bias deviation of monthly means (or daily means) and root mean square deviation of

Solar Irradiance, Global Distribution. Figure 21
Solar surface irradiance for August (*left*) and February (*right*) 2005 (Data source: SRB project)

Solar Irradiance, Global Distribution. Figure 22
Annual mean of solar surface irradiance (SIS, *left*) and direct horizontal irradiance (SID, *right*) over Europe. Even on a small scale it is evident that cloudiness modifies the irradiance distribution. Orographic cloud effects can be seen along the North coast of Spain and the Pyrenees, as well as along the Balkan Mountains and the Alpine region. The low solar irradiance in North-West Europe results from large cloudiness (Data source: CM-SAF, www.cmsaf.eu)

hourly means are given, usually derived by comparison with reference ground-based radiometric stations. Unfortunately, these quantities may not be appropriate to define the accuracy of the data. For gridded solar irradiance data (e.g., remote sensing, reanalysis data) the Root Mean Square Deviation (RMSD) for hourly values is of limited value for the estimation of errors in the predicted solar resource. On an hourly basis, large parts of the deviation are due to the mismatch between the grid size of the data and point-specific ground measurements and, therefore, do not provide reliable information about true accuracy. The bias evaluated in publications is often averaged over several months and measurement stations and provides therefore only limited information on the accuracy of solar irradiance for a specific site and period. The bias contains always a cancellation of errors. For example, a bias of −100 in one region and +100 in another region leads to an overall bias of zero. However, data with such regional bias values might be of limited value. Moreover, averaging bias over time may result in misleading information, e.g., a bias of −20 W/m^2 during winter time and +20 W/m^2 during summer time results in a yearly bias of 0. Hence, neglecting seasonal variation may lead to significant errors in the predicted energy yield of solar systems, for instance. Hence, error information given in publications must be interpreted with care. In order to improve the evaluation of accuracy, CM-SAF introduces three additional accuracy measures, the mean absolute difference, the fraction of month with bias above a certain threshold, and the anomaly correlation. These statistical quantities (error measures) have been introduced for climate monitoring but might be of value for accuracy definition within solar energy applications, too. Table 1 illustrates the shortcoming and partly misleading information about accuracy arising from the use of bias as the main error information.

In the discussion that follows, the selected accuracy measure is the mean absolute deviation and not the bias. Nowadays, monthly means of solar surface irradiance can be retrieved from satellites by state-of-the-art retrieval schemes with an overall accuracy of 8–10 W/m^2 or even better. Accuracy here means mean absolute differences in the order of 8–10 W/m^2, or even below, and that at least 90% of the monthly bias values are below 10 W/m^2 plus the uncertainty of ground measurements of 5 W/m.

Solar Irradiance, Global Distribution. Figure 23

Modification of the TOA irradiance distribution in the absence of clouds (the sky is assumed to be cloudless throughout the globe) by atmospheric attenuation due to water vapor and aerosols for August 2005 (Data source: Surface Radiation Budget Project http://gewex-srb.larc.nasa.gov/. Figure generated with NASA NCAR web plotting tool http://mynasadata.larc.nasa.gov/las/servlets/dataset)

Solar Irradiance, Global Distribution. Table 1 Comparison of different data sources with BSRN ground measurements. GEWEX and ISCCP show low bias values. However, the additional error measures demonstrate the limited value of ISCCP [30] and GEWEX data [31] for solar energy applications. The relative low accuracy is partly a result of the coarse spatial resolution

SSI (monthly)	n_{mon}	Bias W/m^2	MAD W/m^2	SD W/m^2	AC	$Frac_{mon} > 15$ W/m^2 %
CM SAF-BSRN	855	4.40	7.99	8.14	0.89	11.35
GEWEX-BSRN	855	−2.56	12.26	11.12	0.82	32.75
ISCCP-BSRN	855	−0.03	11.79	11.37	0.78	29.94

MAD mean absolute difference of the monthly bias values, *SD* standard deviation, *AC* anomaly correlation and finally the fraction of months with bias larger than 15 W/m^2

Due to the lack of ground measurements, only rudimentary validations can be performed in some regions of the world, e.g., the ocean and large parts of Africa, including the Sahara desert. BSRN has only four well working radiometric stations in Africa. Similarly, data measured by Fluxnet [32] radiometric stations are partly suspicious and cannot be used for validation without sophisticated quality control [33]. Substantial disparities in different solar radiation maps are apparent, in particular in DNI. These differences may arise from the use of different aerosol data sets. However, in regions with a lack of reference data from ground measurements, the reason for differences can only be analyzed rudimentarily. As discussed, the effect of uncertainties and errors in aerosol and cloud classification is much higher on direct irradiance than on (overall) solar surface irradiance, which explains the difficulties to generate consistent and accurate data sets. Gueymard [34] has analyzed the performance of eight DNI datasets (from both free and commercial sources) using high-quality radiation data from 14 sites in North Africa and bordering regions. He found that these datasets are reasonably accurate over southern Europe. Over North Africa and the Middle East, however, the results presented in his study indicate a significantly lower accuracy, and even reveal some important problematic areas. He found a large monthly scatter in many cases. Even the annual mean DNI predictions may be affected by considerable biases (such as for Cairo and Ilorin). Based on an analysis of coincident radiation and aerosol data from collocated instruments, Gueymard showed that, in most cases, these biases are caused by inaccurate aerosol data being used to model DNI. Unfortunately, away from in situ measurements, the available aerosol information is linked with a high uncertainty. Based on recent publications it can be expected that the uncertainty in AOD may be more than $\pm$ 0.1 over many regions of the world. Figure 16 illustrates the large effect of different aerosol climatologies on DNI. Based on these results, it has to be expected that the accuracy of DNI is much lower than that of solar surface irradiance. Suri [35] compared five databases of DNI for Europe.

The average of these databases shows three regions with high annual DNI above 1,800 kWh/m^2 – South and Central Spain and Portugal, Sicily and Provence. The variability defined by the relative standard deviation stays generally within 7–8% for these regions, but for the large Mediterranean islands and parts of Andalusia, a larger variability is apparent.

The DNI resource seems to be significantly lower over South-Eastern Europe and Italy (with the exception of Sicily). However, outdated aerosol information in some of the data bases might have affected the findings of [35]. Here, the data bases show large deviations, hence a higher disagreement (standard deviation sometimes above 20%). North of the Alps, the DNI potential is below 1,400 kWh/m^2 with decreasing values for increasing latitudes. Here, a higher level of disagreement between the data bases can be observed as well. Suri et al. [35] concluded that aerosols are the main cause for the differences between the data bases, which is indeed highly likely for some sunny regions. However, in cloudier regions (Northern part of Great Britain, Belgium, regions close to the North-Sea, Pyrenees, Denmark, coastline of Croatia) it is likely that clouds or fog are the main cause for the large differences between the data bases.

Lohmann [36] found that at least 15 years of DNI data are needed to overcome uncertainties in energy predictions arising from interannual variations in DNI. Of course, well-maintained, ground-based radiometric measurements covering a period of 15 years are not available in the vicinity of most potential solar energy sites. Satellite data cover such long periods, but their accuracy is mostly not well defined and uncertainties caused by inaccurate aerosol information cannot be evaluated without ground measurements. Setting up and maintaining private aerosol and radiometric ground measurements and subsequent operation for decades is very cost intensive and would anyway lead to an unacceptable delay in the planning and construction of solar energy systems. One reasonable option to overcome this problem is the combination of long-term meteorological data gained from existing data sets with shorter-term in situ measurements of solar irradiance at the site of interest. With a sophisticated method such as Model Output Statistics (MOS) or correlation analysis, the long-term data (satellite-derived or reanalysis) can be corrected with reference to short-term ground measurements to obtain an unbiased long-term solar radiation data base. This method is already applied successfully for wind energy planning.

As a result of the discussed uncertainties in existing gridded data sets, it is obvious that there is a need to improve the accuracy and evaluation of these data sets. Moreover, it is evident that additional well-maintained radiometric stations would be very helpful for the validation of gridded data sets and the improvement of solar energy prediction, especially in regions with a pare density of operated meteorological measurements, like Africa.

Figure 24 shows the temporal variability of DNI over the USA derived by analysis of data from the National Solar Radiation Database [37]. The temporal variability is evaluated by the standard deviation of annual means relative to the 8-year long-term mean. The temporal variability is relatively low in areas of low cloudiness (such as the southwest), and may be high in areas where both high cloudiness and complex topography features are present. Figure 25 shows the Direct Normal Irradiance (DNI) for the USA. In the South-West low temporal variability is associated with high DNI values.

Solar Irradiance, Global Distribution. Figure 24

Temporal variation of DNI in the USA, expressed by the coefficient of variation (COV), i.e., the standard deviation divided by the mean. Large regional differences in the interannual variability are obvious. The higher the temporal variability the longer the needed time period to enable an accurate energy prediction (Source: http://rredc.nrel.gov/solar/newdata/variability)

Solar Irradiance, Global Distribution. Figure 25
DNI potential in the USA. The map shows large longitudinal gradients, which are mainly a result of gradients in cloud cover, aerosol load, humidity, and elevation. This Map was produced by the National Renewable Energy Laboratory for the US Department of Energy, 2009, www.nrel.gov. (World maps of solar irradiance, globally or for specific regions, can be obtained (including data download) from http://mynasadata.larc.nasa.gov/las/servlets/dataset)

Summary The distribution of solar irradiance at the top of atmosphere is defined by the Earth-Sun geometry discussed in section "Global Distribution of the Top of Atmosphere Irradiance". The annual mean is only dependent on latitude, with highest values at the equator and lowest values at the poles. The solar irradiance decreases with increasing latitude mostly according to a cosine of latitude. No longitudinal dependency of solar irradiance exists there.

The solar energy potential or solar resource is defined by the solar surface irradiance, which is determined by the solar irradiance at the top of atmosphere and by atmospheric attenuation induced by the atmospheric variables such as water vapor, aerosols, and clouds. The spatial and temporal distribution of these atmospheric variables does significantly affect the distribution of surface irradiance. In contrast to the top of atmosphere distribution, significant latitudinal gradients are apparent in the solar irradiance distribution. As a consequence, the equatorial belt is not the region with the highest solar irradiance, in particular due to the effect of cloudiness.

The distribution of surface irradiance relative to the TOA distribution is essentially defined by the cloud albedo (cloud cover) on a global scale. Main features are the Intertropical Convergence Zone (ITCZ) and mid-latitude with a frequent occurrence of "storms," which are characterized along their tracks by high cloud cover of more than 70%. In Africa and South America the largest amounts of surface irradiance are not located close to the equator, as a consequence of the high cloudiness induced by the ITCZ. The surface irradiance is partly even lower there than in mid-latitudes. The region with maximum surface irradiance over land surfaces is located in a subtropical belt between ca. 15° and 35°N. Around 80% of the solar

surface irradiance is available as direct irradiance in these regions. Many of the developing nations in northern Africa and southern parts of Asia lie within this belt and have therefore optimal conditions for the use of solar energy. Above 35° latitude, the amount of available irradiance decreases with increasing latitude. However, in regions with low cloudiness and air pollution, relative high amounts of solar irradiance are received and thus a good solar energy potential still exists. In general, regions beyond 50° North or South receive much lower amounts of solar irradiance and hence offer less favorable conditions for solar energy systems. This results from a combination of lower solar irradiance at the top of atmosphere and of high cloudiness. For direct irradiance, the effect of clouds and aerosols on its distribution is much more pronounced than in the case of (overall) solar surface irradiance, as a result of the high sensitivity of direct irradiance on these atmospheric variables.

Regions with low cloudiness have a very high solar energy potential. However, in these regions the effect of aerosols becomes relatively more important, especially in the case of direct irradiance. Nowadays it is possible to obtain gridded solar surface irradiance data with an accuracy better than 10 W/m^2. For direct irradiance, less data sets are available and the uncertainty is much larger. This is partly due to the high uncertainty in the available aerosol information, which is, in turn, a result of the quite limited number of stations measuring aerosol properties, which slows scientific progress in this field.

Future Directions

Solar irradiance and its distribution are a driving factor of life on Earth, playing a dominant role in the distribution of climate zones, plants, animals, and to some extent human settlements. In this context, it is important to improve our knowledge of the global distribution of solar irradiance, including issues on accuracy and resolution. In this context, it is also necessary to improve our understanding of the processes affecting the global distribution of solar radiation. While the astronomical physics determining the distribution of solar irradiance at the top of atmosphere is well understood, there are still gaps in our knowledge about the distribution of solar radiation induced by the atmospheric variables. In particular, the accuracy of cloud properties and aerosol properties has to be improved. Also the affect of the greenhouse warming (climate change) on the global distribution of clouds and hence on solar radiation should be investigated in more detail. In turn, it should be investigated in more detail how changes in the global distribution, resulting, e.g., from changes in cloudiness, affect the observation and analysis of greenhouse warming. Increase of cloud albedo can partially compensate greenhouse warming, whereas a decrease in cloud albedo would force further warming [38]. There seems to be also room for improvement in our knowledge of the interaction between solar irradiance distribution and animal, plant, and surface types.

The accuracy of direct irradiance data needs to be improved in order to provide reliable solar radiation data for the energy prediction of solar power plants. Therefore data sets of aerosols with higher accuracy are required. Also, appropriate correction of broken cloud effects is expected to improve the accuracy of satellite-derived direct irradiance data sets. There is still a lack of public-domain solar surface irradiance and direct irradiance data sets. Moreover, the accuracy information in existing data sets needs to be improved by additional accuracy measures and more independent intercomparison studies. In general, the international activities of institutions such as the International Energy Agency concerning quality monitoring and consistency of solar irradiance data sets and algorithms should be intensified. The extension of existing high-quality ground measurement networks such as the BSRN (for solar radiation) and Aeronet (for aerosols) would be very important. This would support scientific developments in various disciplines, such as climate change and solar energy utilization.

Finally, concerning the bridge between natural sciences and social sciences there seems to be a need for an extension of studies concerning the interaction between solar surface irradiance distribution and the history, status, and modifications of cultures. This should also include a discussion of modifications of these interactions due to technical progress and, hence, the interaction between culture and technical adaptations to specific extreme solar irradiance conditions.

Acknowledgments

We acknowledge NCEP/NCAR, SRB/GEWES/NASA for the open, easy and free web access to their high-quality data. Many thanks to Anke Kniffka and Susanne Vlpel for proofreading and to Rebekka Posselt for the seasonal mean figures of solar irradiance.

Glossary

Action spectrum Weighting function describing the wavelength dependence of the biological response. Usually, it is normalized to 1 at a specific wavelength. In the UV, action spectra need to be known accurately over several orders of magnitude.

Direct spectral irradiance $E_{\lambda,D}$ Radiant energy dQ arriving from the disk of the sun per time interval dt, per wavelength interval $d\lambda$, and per area dA on a surface normal to the solar beam.

$$E_{\lambda,D} = \frac{dQ}{dt\, dA\, d\lambda}$$

The angular field of view of an instrument measuring direct normal spectral irradiance must be sufficiently small to reduce uncertainties caused by circumscolar radiation. Recommendations for

view-limiting geometries can be found in WMO [166].

Erythemally weighted irradiance E_{CIE} Global spectral irradiance $E_G(\lambda)$ multiplied with the action spectrum for erythema, $C(\lambda)$, proposed by CIE [1] and integrated over wavelengths λ:

$$E_{CIE} = \int_{250\text{nm}}^{400\text{ nm}} E_G(\lambda) \cdot C(\lambda)\, d\lambda$$

Exposure The spectral exposure Ex_λ is the radiance L_λ integrated over the relevant areas dA of the human body. In this context, the spectral radiance originates from the Sun's direct beam and any scattered components.

$$Ex_\lambda = \int_{t_1}^{t_2} \left(\oint_{(A)} L_\lambda(\varepsilon, \varphi, t, \lambda) \cdot dA \cos\varepsilon \right) dt$$

where $T = t_2 - t_1$ is the exposure time. $Ex_\lambda(\lambda)$ may be weighted with a biological action spectrum and integrated over the wavelength to assess its biological impact. In this case the exposure is no longer a function of the wavelength and has the unit J.

Global spectral irradiance $E_{\lambda,G}$ Radiant energy dQ arriving per time interval dt, per wavelength interval $d\lambda$, and per area dA on a horizontally oriented surface from all parts of the sky above the horizontal, including the disk of the sun itself:

$$E_{\lambda,G} = \frac{dQ}{dt\, dA\, d\lambda} = E_{\lambda,D} \cdot \cos(\vartheta) + E_{\lambda,S}$$

where ϑ is the solar zenith angle.

Spectral radiance L_λ, This can be defined in terms of emitted or received radiation. Here the latter applies. Radiant energy dQ per time interval dt, per wavelength interval $d\lambda$, per area dA, and per solid angle $d\Omega$ on a receiver oriented normal to the source.

$$L_\lambda = \frac{dQ}{dt\, dA\, d\lambda d\Omega}$$

UV index A measure of solar UV radiation at the Earth's surface that is used for public information. According to [2], the UV index is calculated considering the following items:

1. Calculation of the erythemally weighted irradiance E_{CIE} (see above) by utilization of the CIE action spectrum [1] normalized to 1.0 at 298 nm.
2. A minimum requirement is to report the daily maximum UV index.
3. The index is expressed by multiplying the weighted irradiance in W m^{-2} by 40.0 (this leads to an open-ended index which is normally between 0 and 16 at sea level, but with larger values possible at high altitudes).

Remarks:

(a) The definition of the UV index given above may be revised in the future.
(b) According to the alternative definition given in [3], the UV index is calculated as the daily maximum erythemally weighted irradiance in W m^{-2}, averaged over a duration of between 10 and 30 min and multiplied by 40.

UV-A radiation Electromagnetic radiation between 315 and 400 nm [4]. UV-A radiation is a summarizing term only and, unlike UVA irradiance, not a physical quantity.

UV-B radiation Electromagnetic radiation between 280 and 315 nm [4]. UV-B radiation is a summarizing term only and, unlike UVB irradiance, not a physical quantity.

Vitamin D Vitamin D is produced photochemically by UV exposure and conversion of 7-dehydrocholesterol into previtamin D_3, which is rapidly converted to vitamin D_3. The active form of vitamin D_3, 1,25-dihydroxyvitamin D_3, is a hormone.

Definition of the Subject

Solar radiation has both direct and indirect impacts on human health. Only direct effects are described here. (Space is too limited to describe the indirect effects, which are numerous, complex and imbedded into important feedback mechanisms; the most important indirect effects for human health are on the availability and quality of food, effects on aquatic and terrestrial plants and ecosystems, deterioration in air quality, damage to materials, and energy-related issues that drive the world economy.)

While solar energy has been stored in the form of oil and gas for millions of years, it has become evident that these resources are limited and that harnessing renewable energies will be necessary in the future. Closely related are the effects on the environment for food production, which relies on solar energy.

The sun's spectrum extends over a much-broader range of wavelengths than what is detected by the human eye, which responds only from 380 (violet light) to 780 nm (red light), with a peak response near 550 nm (green light). About 50% of the total solar irradiance originates from the near-infrared region. A relatively small but nevertheless important component is contained in the ultraviolet (UV).

Usually, any effect of solar radiation on biological organisms is wavelength dependent. A frequent concept is to describe these effects by means of biological weighting functions, often called action spectra, which quantify the wavelength dependence of effects introduced by electromagnetic radiation on biological matter. Depending on the effect and the organism involved, different biological weighting functions $W(\lambda)$ are used. The biologically effective irradiance, E_{weighted}, is calculated by multiplying the global spectral irradiance, $E_G(\lambda)$, with the action spectrum $W(\lambda)$, and integrating over wavelengths λ:

$$E_{\text{weighted}} = \int E_G(\lambda) \times W(\lambda)\, d\lambda$$

Note that the equation above is applicable for additive effects only (the so-called Bunsen–Roscoe law). Whether the concept is applicable or not must be proven or judged for each individual case. An important weighting function is the action spectrum for erythema (sunburn), as proposed by CIE [1], which describes the wavelength dependence of the reddening of human skin by UV radiation (see also below "erythemally weighted irradiance" E_{CIE}).

Introduction

Humans have long been aware of a close relationship between human health and solar radiation. This is reflected by the fact that in many religions, the sun plays an important role. In many ancient cultures, the sun itself was considered as a god (e.g., in Egypt). The systematic study of the effects of solar radiation progressed in parallel with the evolution of science and medicine. For an assessment of the spectral dependencies of solar radiation, a separation of the different spectra was necessary. A major step was probably the analysis by Joseph von Fraunhofer in the early nineteenth century, who separated the different components of sunlight with high precision using his newly constructed prisms. Later on, the investigations carried out by Carl Dorno, and his publication about "light and air in mountainous regions" that he published in 1911, were other important milestones. For a long time, the UVB radiation was actually called "Dorno radiation."

In this chapter, the present knowledge of the relationship between solar radiation and human health is described. Historical aspects, which are course interesting in their own right, are not considered further. This chapter is separated into the knowledge of spectral effects (UV, visible, and infrared), followed by a short section that deals with effects for which the spectral dependence is not yet known. Solar radiation has both negative and positive effects on human health. The negative effects of UV radiation have been emphasized in recent decades – on the background that skin cancer has been the cancer with the highest rate of increase. In recent years, however, more attention is being given to the positive side of solar radiation. At the end of this chapter, the benefits and dangers of solar radiation are summarized.

UV Radiation and Health Effects

The atmosphere is largely transparent in the visible region. Conversely, gaseous absorption is important in the UV. The latter is subdivided into three spectral bands: UV-A (315–400 nm) radiation, UV-B (280–315 nm) radiation, and UV-C (100–280 nm) radiation. (some authors still use 320 nm as the boundary between UV-A and UV-B radiation.) This separation has been originally introduced due to its relation with human effects. Nowadays, it is better understood that these effects cannot be strictly separated and, thus, only the general term "UV" is often used. UV-A radiation is largely unaffected by gases in the atmosphere. Conversely, only a small amount of UV-B radiation proceeds to the Earth's surface because it is strongly

absorbed by atmospheric ozone, whose absorption cross section increases rapidly toward shorter wavelengths in this spectral region. UV-C comprises less than 0.6% of the incident solar spectrum at the top of the atmosphere, but none of it reaches the surface. Radiation below 240 nm is absorbed by molecular oxygen (O_2, which comprises 20% of the atmosphere). This radiation is capable of photo-dissociating molecules to form two oxygen atoms. The atoms so formed then recombine with another oxygen molecule to form ozone (O_3). Under the terms of the Montreal Protocol on Protection of the Ozone Layer, assessments of the knowledge about the science of Ozone Depletion and UV radiation [5, 6] and assessments of the Environmental Impacts of Ozone Depletion [7] are produced regularly.

If human eyes were sensitive to UV radiation rather than to visible radiation, perceptions of the world would be very different. The sky appears blue because air molecules scatter blue light more strongly than red light. This dependence on the wavelength (λ) of light is very strong. Rayleigh scattering theory shows that it varies as λ^{-4} so, at 300 nm, the strength of this scattering is about 32 times greater than at 600 nm. That is why photographers choose to use blue-blocking filters (i.e., red filters) if they want to obtain dramatic images of cloudy skies in black and white pictures since such filters can greatly enhance the contrast between the bright cloud and dark background.

Because of this wavelength-dependent scattering by air molecules, the UV radiation field is much more diffuse than visible radiation (light). An eye sensitive to UV radiation would therefore perceive a much smaller contrast between clouds and sky, and a smaller contrast between sky and sun. Under clear skies, the diffuse UV component would normally dominate over the direct beam component, whereas in the visible, the diffuse component is typically only 5–15% of the direct. When the sun is low in the sky, Rayleigh extinction becomes so large that the solar disk in the UV region would not even be detectable from the surrounding skylight. The sphere of consciousness would be greatly reduced because objects more distant than even a few kilometers would be completely lost in the gloom of diffuse light. It would be like living in a light fog. Shadows would be less distinct. When the sky is overcast, places normally in the shade would receive more light than under clear skies. One practical implication of this more diffuse field is that any reduction in UV radiation in a shaded area is smaller than the reduction in visible light, as perceived with the eye. Therefore, the protection from the sun offered by shade may be less complete that anticipated from the standpoint of UV effects. The brightness of objects would appear very different too. Most natural surfaces reflect a significant fraction of the incoming visible radiation. But in the UV region, very few surfaces are strongly reflecting. Most natural surfaces would appear quite dark because they reflect less than 5% of the incoming UV-B radiation. Snow and clouds are two of the few exceptions to this rule.

Another aspect of UV radiation is the ratio of diffuse to direct irradiance is much higher in the UV compared to visible wavelengths. Therefore, under clear skies, hazy skies, or very lightly cloudy skies, the diffuse UV irradiance comes from all possible directions, rather than preferentially from around the sun disk (Fig. 1). This further decreases the effectiveness of partial shading structures.

The variability in UV irradiance between common sources is described in Table 1.

Vitamin D

Vitamin D Metabolism Solar UV-B irradiation (280–315 nm) of the skin is the major source of vitamin D3 for humans, whereas dietary intake of vitamin D2 or vitamin D3 is a second, less important source. The dietary contribution to vitamin D supply usually does not exceed 10–20% in free-living persons. Only few fatty salt water fish such as herring, salmon, and sardines are good sources of vitamin D. Skin synthesis of vitamin D3 is very effective. The relevant quantity is the exposure, as defined above (in units of W). Some authors consider summer exposure of arms and legs for 5–30 min (depending on latitude and skin pigmentation) between the hours of 10 a.m. and 3 p.m. twice a week to be adequate. However, it has been found that the vitamin D action spectrum is more uncertain than previously thought. Consequently, in winter, it may not be possible to gain enough vitamin D by casual exposure to sunlight. Exposure of skin to sunlight at regular intervals results in the photochemical conversion of 7-dehydrocholesterol into previtamin D_3, which is rapidly converted to vitamin D_3. In the midsummer

Solar Radiation and Human Health. Figure 1

Radiance distribution measured during clear skies in Hannover during noon. The position of the sun – south at noon – is given by the white symbol. *Left* panel 305 nm, *right* panel 500 nm. It can be recognized that the spatial distribution is quite different at these two wavelengths and that the distribution of sky radiance is more uniform in the UV, which can be understood as a result of double scattering by Rayleigh scattering

months (e.g., June and July in the northern hemisphere), the amount of vitamin D_3 increases to a maximum of approximately 12% of the amount of 7-dehydrocholesterol at latitudes of 34° and below, to 9% in one hour in Boston (42° N) and 11% in 3 h in Edmonton (52° N). Analyses after exposure of the 7-dehydrocholesterol solution at several places in the southern hemisphere showed concordant results [8]. The sunlight-generated vitamin D_3 is a precursor of the active hormonal form of vitamin D_3. Because any excess in previtamin D3 or vitamin D3 is destroyed by sunlight, excessive exposure to sunlight does not cause vitamin D intoxication. It has been reported that exposure to one minimal erythemal dose while wearing only a bathing suit is equivalent to ingestion of approximately 500 μg of vitamin D [9]. Because of its skin synthesis, vitamin D_3 is not really a vitamin for humans. However, if skin exposure to UV-B radiation is negligible (e.g., in winter) or if people live exclusively indoors (institutionalized people), then there is indeed an absolute regular requirement for the fat soluble vitamin D, which must be met through proper dietary intake.

Once in circulation through the body, vitamin D is metabolized by a hepatic hydroxylase into 25-hydroxyvitamin D (25[OH]D) and by a renal 1α-hydroxylase into the vitamin D hormone 1,25-dihydroxyvitamin D (1,25-dihydroxyvitamin D) (Fig. 2). The latter step is under the control of parathyroid hormone (PTH) and serum phosphate. However, in case of vitamin D deficiency/insufficiency, renal synthesis of 1,25-dihydroxyvitamin D becomes substrate dependent, i.e., dependent on the circulating 25(OH)D concentration [10].

The active form of vitamin D, 1,25-dihydroxyvitamin D, is known as a regulator of systemic calcium homeostasis. Together with the parathyroid hormone (PTH) and calcitonin, 1,25-dihydroxyvitamin D carries out the policing job of regulating serum calcium levels in highly evolved

Solar Radiation and Human Health. Table 1 Relationships between various weightings for a typical dermatological UV-A tanning salon compared with natural sunlight (noon sun in summer and winter at 45° S (Lauder New Zealand) and a powerful 1,000 W quartz halogen lamp at a distance of 0.5 m. UV_Ery and UV-VitD are erythemally weighted and vitamin D-weighted UV radiation, respectively

Quantity	Unit	UV-A tanning salon	Winter sun	Summer sun	1,000 W FEL at 0.5 m
UV-A	(μW cm^{-2})	17,598	1797	6161.5	106.2
UV-B	(μW cm^{-2})	208.3	17.9	206.6	6.6
UV_Ery	(μW cm^{-2})	51.5	2.6	28.2	7.0
UV_VitD	(μW cm^{-2})	63.8	3.2	56.7	3.8
UVI		20.6	1	11.3	2.8
T(2SED*)	(min)	6.5	128.2	11.8	47.4
Vit. D/Ery		1.2	1.2	2	0.5
UV-B / UV-A		0.012	0.010	0.034	0.062

mammals. This regulating mechanism is done with astounding efficiency, indicating the importance of serum calcium homeostasis. Serum calcium homeostasis is essential for blood coagulation, activation of various intracellular processes, and bone health. Therefore, serum calcium level of 2.5 mmol/L is maintained in all vertebrate life forms (both aquatic and terrestrial). The regulatory system of calciotropic hormones appears to have developed after transition of life from water (calcium–phosphorus rich environment) to land (environment poor in calcium and phosphorus). This assumption is supported by the fact that, in fish, PTH is missing and calcitonin is inactive [11]. Together with PTH, vitamin D is responsible for maintaining serum calcium levels by increasing intestinal calcium absorption, renal calcium reabsorption, and calcium resorption from bone. Without vitamin D, only 10–15% of dietary calcium and about 60% of phosphorus can be absorbed. vitamin D increases the efficiency of intestinal calcium absorption to 30–40% and phosphorus absorption to approximately 80% [11].

1,25-dihydroxyvitamin D also plays a pivotal role in the intracellular calcium homeostasis and has pleiotropic effects in various tissues. The biological actions of 1,25-dihydroxyvitamin D are mediated through the vitamin D receptor (VDR). In this context, 1,25-dihydroxyvitamin D functions as a steroid hormone that binds to a cytosolic VDR, resulting in a selective demasking of the genome of the nucleolus. The vitamin D receptor is nearly ubiquitously expressed, and almost all cells respond to 1,25-dihydroxyvitamin D exposure. About 3% of the human genome is regulated, directly and/or indirectly, by the vitamin D endocrine system [12]. Apart from the kidney, 1,25-dihydroxyvitamin D can be locally produced in several tissues. These tissues include monocytes, dendritic cells, B lymphocytes, colonocytes, vascular smooth muscle cells, and endothelial cells. Consequently, for 1,25-dihydroxyvitamin D, a paracrine role separate from its calcium-regulating function has been proposed.

Reference Values There is general agreement that the measurement of 25(OH)D is the appropriate tool for the assessment of vitamin D status. Nevertheless, there is currently no consensus on adequate/optimal circulating 25(OH)D concentrations. Cutoff values range between 50 nmol/L [13], 90–100 nmol/L [14], and more than 100 nmol/L [15]. This inconsistency is in part due to different criteria of defining inadequacy. Many researchers do not differentiate between different stages of vitamin D status. However, similar to other vitamins, it is possible to categorize the stages of vitamin D status into deficiency, insufficiency, hypovitaminosis, adequacy, and intoxication. In the deficiency range, severe vitamin D-specific clinical symptoms such as rickets, osteomalacia, calcium malabsorption, severe hyperparathyroidism, low 1,25-dihydroxyvitamin D concentrations, impaired immune system, and ultimately death can occur. In the insufficiency range, reduced bone mineral density, impaired muscle function, low intestinal calcium absorption rates, elevated PTH levels, and slightly reduced 1,25-dihydroxyvitamin D concentration are encountered. In the stage of hypovitaminosis, the body's vitamin reserves are already low, and slightly enhanced PTH levels may be present,

Solar Radiation and Human Health. Figure 2
Vitamin D metabolism

although the corresponding concentrations are usually still in the reference range. In the stage of adequacy, no disturbances in vitamin D-dependent body functions do occur. Only excessive oral intake can lead to vitamin D intoxication, resulting in intestinal calcium hyperabsorption, hypercalcemia, soft tissue calcification, and death. On an individual basis, the consequences of an insufficient vitamin D status may be mild, but the consequences on a population scale may be more important because of the large number of people who are affected. People with long-lasting vitamin D insufficiency may have the highest risk to develop vitamin-D-related chronic diseases.

Unfortunately, insufficient vitamin D status is prevalent around the world. Over the six regions Asia, Europe, Middle East and Africa, Latin America, North America, and Oceania, it has been found that between 50% and more than 90% of people have 25(OH)D concentrations below 50 nmol/L [16]. Low vitamin D status is most common in South Asia and the Middle East. Insufficient vitamin D status and even vitamin D deficiency is widespread, and is actually reemerging as a major health problem globally. Urbanization is an important risk factor for vitamin D insufficiency/deficiency in large parts of the adult population. Other factors include short daylight periods, long cold or hot seasons – or strict cultural traditions – imposing extensive clothing, modern and also traditional lifestyles such as indoor working, predominantly indoor leisure time activities, and the aging factor (institutionalization of elder persons). In a British study in the 1958 birth cohort, for example, 25-hydroxyvitamin D concentrations below 40 nmol/L were more prevalent in Scotland than in the South of England [17]. In highly urbanized or polluted areas, individual daily sun exposure is usually too low to achieve a 25(OH)D level of 75 nmol/L. Without food supplementation, the diet is then not able to close the gap in vitamin D supply. There have been studies linking vitamin D deficiency to latitude [18–21], but there are also studies that could not confirm such correlations [22].

Musculoskeletal Disease Urbanization and industrialization (with their associated air pollution problems) have long been known as a major cause of childhood rickets in western countries. Rickets is now on the increase in many developing countries and is also reemerging as an important health problem in countries with strong sun avoidance policies, or in cultures requiring strictly modest dressing codes. In adults, severe vitamin D deficiency causes osteomalacia, a disease resulting in bone demineralization and muscle weakness.

Due to low calcium absorption rates, vitamin D insufficiency can also contribute to the bone disease osteoporosis. It is estimated that up to 50% of women and more than 20% of men 50 years of age or older will sustain an osteoporotic fracture in their remaining lifetime. A meta-analysis of randomized clinical trials that evaluated the effect of vitamin D supplementation came to the conclusion that the fracture preventing effect of vitamin D is approximately 20% when serum 25(OH)D levels of 75–80 nmol/L are achieved [23]. Another meta-analysis of randomized controlled trials (RCTs) came to the conclusion that daily doses of 17.5–20 μg supplemental vitamin D are able to prevent elderly adults to fall down by improving muscle function [24]. The relative risk of falls was reduced by approximately 20% when serum 25(OH)D concentrations of 60 nmol/L or more could be maintained. In contrast to "high-dose" supplemental vitamin D, low-dose daily supplemental vitamin D (5–15 μg) is not able to prevent falls.

Cancer Since vitamin D is a key regulator of various cellular metabolic pathways, it is important for cellular maturation, differentiation, and apoptosis [25]. In 2008, the WHO published a report from the International Agency for Research on cancer [26] that came to the conclusion that there is (1) consistent epidemiological evidence for an inverse association between 25(OH)D and colorectal cancer and colorectal adenomas, (2) suggested epidemiological evidence for an inverse association between 25(OH)D and breast cancer, (3) insufficient evidence for an inverse association between 25(OH)D and other types of cancer, and (4) the need for new RCTs. One such RCT has recently been published [27]: In a 4-year, population-based study, where the primary outcome was fracture incidence and the principal secondary outcome was cancer incidence, 1,179 community-dwelling women were randomly assigned to receive 1,500 mg supplemental calcium/day alone (Ca-only), supplemental calcium plus 27.5 μg vitamin D/day (Ca + D), or placebo. The cancer incidence was 60–77% lower in the Ca + D women and 43% lower in the Ca-only group than in the placebo control subjects ($P < 0.03$).

Diabetes Mellitus In vitro and in vivo studies suggest that vitamin D can prevent pancreatic beta-cell destruction and reduce the incidence of autoimmune diabetes. This may be due, at least in part, to a suppression of proinflammatory cytokines such as the tumor necrosis factor (TNF)-α. Recently, the relationship between UVB irradiance and age-standardized incidence rates of type-1 diabetes mellitus in children aged 14 years or less was analyzed according to 51 regions of the world [28]. Incidence rates were generally greater at higher latitudes and were inversely associated with UV-B irradiance. As early as 2001, Hyppönen et al. [29] demonstrated, in a birth cohort study, that vitamin D supplementation was associated with a decreased frequency of type-1 diabetes. In contrast, children suspected of having rickets during the first year of life had a three times higher relative risk compared with those without such a suspicion. A meta-analysis of four case-control studies has shown that the risk of type-1 diabetes is reduced by 29% in infants who are supplemented with vitamin D compared to those who are not supplemented [30]. There is also some evidence of a dose-response effect, with those using higher amounts of vitamin D being at lower risk of developing type-1 diabetes.

Observational studies, e.g., Pittas et al. [31], show a relatively consistent association between low vitamin D status and prevalent type-2 diabetes, with an odds ratio of 0.36 for highest vs. lowest 25-hydroxyvitamin D among nonblacks. Evidence from RCTs with vitamin D and/or calcium supplementation suggests that combined vitamin D and calcium supplementation may have a role in the prevention of type-2 diabetes only in populations at high risk (i.e., individuals with glucose intolerance). Whereas vitamin D supplementation did not improve glycemic control in diabetic subjects with initial serum 25(OH)D levels above 50 nmol/L [32], administration of 100 μg vitamin D3 improved insulin sensitivity in vitamin D deficient and insulin-resistant South Asian women [33]. Insulin resistance was most improved when endpoint serum 25(OH)D reached at least 80 nmol/L. Optimal vitamin D concentrations for reducing insulin resistance were shown to be 80–119 nmol/L.

Cardiovascular Disease Globally, cardiovascular disease (CVD) is the number one cause of death. In 2005, it was responsible for approximately 30% of deaths worldwide. CVD includes various illnesses such as

coronary heart disease, peripheral arterial disease, cerebrovascular disease such as stroke, and congestive heart failure. There is accumulating evidence that the vitamin D hormone 1,25-dihydroxyvitamin D exerts important physiological effects in cardiomyocytes, vascular smooth muscle cells, and the vascular endothelium. The mechanisms have been reviewed in detail elsewhere [34]. Hypertension is a key risk factor for CVD. A recently published systematic review and meta-analysis came to the conclusion that vitamin D produces a fall in systolic blood pressure of −6.18 mmHg and a nonsignificant fall in diastolic blood pressure of −2.56 mmHg in hypertensive patients. No reduction in blood pressure is seen in studies examining patients who are normotensive at baseline [35].

Several large prospective observational or cohort studies have demonstrated that a higher vitamin D status is associated with approximately 50% lower cardiovascular morbidity and mortality risk compared with low vitamin D status (Table 2).

Mortality In 2007, a meta-analysis was published, including RCTs on vitamin D and mortality that were not primarily designed to assess mortality [29]. The authors concluded that vitamin D supplementation is linked to lower all-cause mortality rates in middle-aged and elderly patients with low serum concentrations of 25(OH)D than in unsupplemented subjects. Daily doses of vitamin D ranged between 10 and 50 μg. Risk reduction was 7% during a mean follow-up of 5.7 years. Several large prospective cohort studies published in 2008 and 2009 have provided further evidence for association of low circulating 25(OH)D levels with enhanced all-cause mortality (Table 3). However, there is some concern that vitamin D has a biphasic effect on mortality with an enhanced risk at deficient 25(OH)D levels but also at levels above 125 nmol/L [41]. The scientific background of this point of view has recently been questioned [42].

Sunburn (Erythema)

Since UV radiation is not detected by the human eye, or by usual light meters, a different standard is needed to quantify how much of it is present at any time. The erythemally weighted irradiance is defined as above, in units of W m^{-2}. For health purposes, the erythemally weighted UV irradiance is generally reported to the public in terms of a dimensionless number called the UV Index (i.e., UVI, – see below). Rather than referring to the response of the human eye (i.e., the "photopic" response) for light, it refers to the response of human skin to sunburn (i.e., the "erythemal" response), which has no contribution from visible radiation but increases rapidly toward shorter wavelengths within the UV range.

Solar Radiation and Human Health. Table 2 Evidence for association of circulating 25-hydroxyvitamin D level with cardiovascular morbidity and mortality

Study	Design	Population	Comparator	Odds/hazard ratio or Relative risk (95% CI)
Fatal stroke [36]	Prospective cohort study with coronary angiography	3,258	Per z value of 25(OH)D	OR 0.58 (0.43–0.78)
Cardiovascular morbidity [37]	Prospective observational study	1,739	25(OH)D > 37.5 nmol/L vs. < 25 nmol/L	HR 0.55 (0.32–0.97)
Myocardial infarction [38]	Nested case control study	1,354	25(OH)D > 75 nmol/L vs < 37.5 nmol/L	RR 0.48 (0.28–0.81)
Cardiovascular mortality [39]	Prospective cohort study with coronary angiography	3,258	Median 25(OH)D 70 nmol/L vs 19 nmol/L	HR 0.45 (0.32–0.64)
Cardiovascular mortality [36]	Prospective observational study in individuals 50–75 years	614	Three highest vs. lowest 25 (OH)D quartile	HR 0.19 (0.07–0.50)
Cardiovascular mortality [40]	Prospective observational study in individuals > 65 years.	3,408	25(OH)D > 100 nmol/L vs < 25 nmol	HR 0.42 (0.21–0.86)

Solar Radiation and Human Health. Table 3 Evidence for association of circulating 25-hydroxyvitamin D level or vitamin D supplementation with all-cause mortality

Study	Design	Population	Comparator	Hazard ratio or relative risk (95% CI)
[43]	Meta-analysis of 18 vitamin D supplementation studies	57,311	Supplemented vs unsupplemented	RR 0.93 (0.87–0.99)
[39]	Prospective cohort study with coronary angiography	3,258	Median 25(OH)D 70 nmol/L vs 19 nmol/L	HR 0.48 (0.37–0.63)
[44]	Prospective observational study in postmenopausal women	1,232	$\geq$ 50 nmol/L vs. $<$ 50 nmol/L	HR 0.46 (0.27–0.79)
[45]	Prospective cohort study in patients with colorectal cancer	304	Mean 41 nmol/L vs. 100 nmol/L	HR 0.52 (0.29–0.94)
[40]	Prospective observational study in individuals $>$ 65 years.	3,408	25(OH)D $>$ 100 nmol/L vs $<$ 25 nmol/L	HR 0.55 (0.34–0.88)
[36]	Prospective observational study in individuals 50–75 years	614	Three highest quartiles vs. lowest quartile	HR 0.51 (0.28–0.93)

Although UVI was developed to represent damage to human skin, it may be applied to other processes because many biological UV effects have similar action spectra. Since UVI is based on the erythemal action spectrum, its sensitivity to ozone change is the same as for erythema. For a 1% reduction in ozone, UVI increases by approximately 1.1%. The UVI is an open-ended scale. In the British Isles, it peaks at ~6, whereas at northern midlatitudes, it peaks at ~10. Peak values are higher in the southern hemisphere because of the lower ozone amounts, closer summertime Sun–Earth separation, and generally cleaner air. For example, the peak UVI in New Zealand is approximately 40–50% larger than at corresponding northern latitudes, and it often exceeds 12 [46]. In the tropics, it is even much higher. The highest values on Earth occur in the Peruvian Andes at latitudes 10–15° S, where UVI can reach 25 [47]. Outside the Earth's atmosphere, the UVI would be ~300.

The relatively high UV levels in New Zealand and Australia [46, 48] are a contributing factor to the high rates of skin cancer in those countries. There are other factors, however. For those of European extraction, skin types are better adapted to the lower UV levels in Europe, especially in the north [48]. Outdoor lifestyle choices can also be important. In temperate climates, it is quite comfortable to spend long periods of time in direct sunlight. The folly of that behavior manifests itself only later – when the discomfort of sunburn is felt, and much later when skin cancer is experienced.

UV Index

Sunburning UV is often reported to the public in terms of UVI. The upper panel in Fig. 3 shows the spectral UV irradiance for two sun angles and an ozone column of 300 Dobson Units (DU) (Note the log scale for the y-axis). The erythemal (i.e., the "skin-reddening," or "sunburning") weighting function is shown on the right axis. The lower panel shows the corresponding spectra of erythemally weighted UV irradiance (UV_{Ery}).

The internationally agreed UVI is defined in terms of UV_{Ery}. The weighting function involves an arbitrary normalization to unity at wavelengths shorter than 298 nm, so UV_{Ery} is not strictly an SI unit. Furthermore, when UV information was first provided to the public, another normalization was applied to give a maximum UVI of ~10 in Canada, where it was first used. The UVI is therefore a unitless number corresponding to the integral under the curves in the lower panels, multiplied by 40 m^2/W. Mathematically,

$$\mathrm{UVI} = 40 \int \mathrm{I}(\lambda)\mathrm{w}(\lambda)d\lambda,$$

where

λ is the wavelength in nm

Solar Radiation and Human Health. Figure 3

Upper panel: UV irradiance spectra for noon sunlight at midlatitude (45° S) in summer and winter. The *grey* line shows the erythemal action spectrum. Note the logarithmic scale on the y-axis. *Lower panel*: The same solar irradiance spectra weighted by the erythemal action spectrum

$I(\lambda)$ is the irradiance in W m^{-2} nm^{-1} and
$w(\lambda)$ is the erythemal weighting function, defined as:

$w(\lambda) = 1.0$ for $250 < \lambda \leq 298$ nm

$w(\lambda) = 10^{0.094(298 - \lambda)}$ for $298 < \lambda \leq 328$ nm

$w(\lambda) = 10^{0.015(139 - \lambda)}$ for $328 < \lambda \leq 400$ nm

$w(\lambda) = 0.0$ for $\lambda > 400$ nm

Exposure Times to Optimize Health Effects of UV Radiation

Attempts have been made to estimate the exposure times from sunlight to optimize health [49]. Results are given in terms of UVI (Fig. 4). The exposure times also depend on skin type and possible application of any sunscreens. In the case of vitamin D production, the optimal exposure time also depends on the area of skin exposed. There is a huge variation between the optimal exposure times in summer and winter at mid-latitude sites. There is no simple relationship between UVI and visible radiation. In the case of sunlight, it is true that as light levels increase, so does UV radiation, but the relationship is complex and nonlinear.

The large seasonal variations are also a health risk. In winter, the UV irradiation may not be high enough to maintain adequate vitamin D. The problem is exacerbated because the skin becomes tanned to protect the body from further damage in summer, and this tan persists into the winter, therefore inhibiting the ability to absorb further UV radiation. Those with darker skins (e.g., Africans, many Maoris, Pacific Islanders, and Asians) are at greater risk.

Some published weighting functions for vitamin D production are similar to that for erythema but do

Solar Radiation and Human Health. Figure 4
Approximate exposure times leading to erythema or to sustained adequate vitamin D production, as a function of UVI. Exposure times corresponding to the *red*-shaded area represent too much UV, leading to erythema (skin reddening- and sunburn). Exposures within the dark *blue* region represents too little UV to maintain an intake of 1,000 IU with full-body exposure. The *unshaded* area represents the range of times for optimal exposure, assuming only the hands and face are exposed. The other *blue* curves give the lower exposure limits for adequate vitamin D for different areas of skin exposed. All times shown are for fair skin (skin type II). For brown skin or black skin (skin types IV and VI), all exposure times should be multiplied by 2 and 5, respectively

not extend as far into the UV-A region. Consequently, it is a stronger function of ozone amount and sun angle. Nevertheless, the minimum exposure time for sufficient vitamin D production may still be estimated in terms of UVI. It also depends on the skin type, the SPF of any sunscreen applied, and the area of skin that is exposed to sunlight. The estimated exposure times for sufficient vitamin D production are compared with the exposure times for erythema in Fig. 2 [49].

In summer, when UVI can exceed 10, skin damage occurs in about 15 min for fair-skinned people, whereas for full-body exposure sufficient vitamin D can be produced in less than 1 min. In winter, when the maximum UVI is ~1, skin damage occurs in 150 min, and even with full-body exposure (unlikely in winter), it would take at least 20 min to produce sufficient vitamin D. If only the hands and face are exposed, there is only a small margin between receiving too little or too much UV; and in winter, it would be impossible to receive sufficient vitamin D without skin damage. For darker skins, or if sunscreens are applied, these exposure times must be increased.

Note that there are large uncertainties in these relationships. Firstly, the action spectra may not be correct; secondly, the relevant quantity is really the irradiance on the surface of the body, rather than on the assumed horizontal surface; and thirdly, both the sensitivity of skin to damage and its ability to synthesize vitamin D depend on previous exposure and on the anatomical site [50, 51].

Skin Cancer

Three types of skin cancer, basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and malignant melanoma (MM), sum up to the most frequent type of cancer in the white population worldwide. For MM, the incidence increases more rapidly than for any other type of cancer. Data for the non-melanocytic skin cancers, NMSCs (BCC and SCC), for e.g., USA and Germany show incidences in the range of 1,000,000 new cases per year (USA, 2005) [52] and about 100,000 new cases per year (Germany, 2003) [53]; 80% of these are found on sun-exposed areas of the human body [54].

Corresponding numbers for MM (the most deadly skin cancer, 20–25% of diagnosed patients die) are about 62,000 new cases per year (USA, 2006) [55] and about 15,000 (Germany, 2004, Robert-Koch-Institut: http://www.rki.de). Most of melanoma cases occur on sun-exposed areas of the body. The estimated 10-year survival rates for patients without evident metastases range from 88% for those patients with tumors smaller than 1mm without ulceration, to 32% for those patients with tumors larger than 4 mm with ulceration [56].

The skin cancer incidence is still increasing in most countries [57, 58], although some stabilization has been observed for parts of western Europe and Scandinavia [59, 60]. Nevertheless, being the most frequent cancer, skin cancer represents a huge problem for the public. The personal, medical, clinical and, last but not least, the final burden of skin cancer has therefore to be reduced by means of primary prevention and early detection.

Environmental Risk Factor(s) Although environmental arsenic exposure [60] or certain types of human papillomaviruses (as cofactors in association with UV) [61], as well as ionizing radiation [62] have been considered to play a role during the pathogenesis of NMSC, the overwhelming number of epidemiological and experimental investigations recognize UV-radiation as the main environmental risk factor [63–68]. The role of UV-radiation in melanogenesis has been discussed in past decades because the MM etiology strongly depends on genetic predispositions (e.g., allelic variances in the melanocortin 1 receptor [69]). However, recent epidemiological and experimental investigations, which are mainly dealing with UV-associated induction of benign nevi and the UV-induced mutation patterns, e.g., in the *BRAF* – gene (in nevi), clearly underline once more the important role of UV-radiation as a risk factor for malignant melanoma [63, 70–74]. It is furthermore important to consider that different types of skin cancer have a different dependence on UV-exposure patterns. Whereas MMs are mainly induced by intermittent UV-exposure (e.g., sunburns) [63, 71, 72], SCC-induction is highly dependent on cumulative UV-exposure, and BCC-induction depends on both cumulative and intermittent exposure patterns [63].

Because the main environmental risk factor in the etiology of skin cancer – UV-radiation (regardless of

natural (sun) or artificial (sunbeds) origin) – is known, skin cancer is one of the key cancers that can be prevented by means of primary prevention (i.e., avoiding or reducing risks).

The importance of UV-radiation as *the* environmental (and artificial) risk factor for the induction of skin cancer has recently been underscored by the International Agency for the Research of Cancer (IARC) which characterized UV-radiation from the sun (and from sunbeds) as a group-1 carcinogen ("carcinogenic to humans") [75]. IARC has also been able to show in a meta-analysis that regular use of sunbeds before the age of 35 increases melanoma risk later in life by 75% [76].

Biological Damage Leading to Skin Cancer UV-photon absorption of DNA leads to photochemical conversion of absorbed energy into photodimerization between adjacent pyrimidine bases. According to an action spectrum, UVB is about 1,000 times more effective than UVA in inducing this kind of photodimerization [77]. UVB also induces, at a much lower frequency, inter- and intra-strand crosslinks, protein-DNA crosslinks, DNA strand-breaks, and rare base adducts [78–80]. Photodimerizations between adjacent pyrimidine bases are by far the most prevalent photoreactions resulting from the direct action of UV-radiation. Two major photoproducts are formed via this reaction pathway: the cyclobutyl pyrimidine dimer (CPD) and the pyrimidine(6–4)pyrimidone photoproduct (6-4PP). CPDs are formed between adjacent pyrimidines linked by a cyclobutyl ring between the five and six carbons of adjacent thymine (Thy) and/or cytosine (Cyt) bases. The 6-4PP links the 6 carbons on a 3' Cyt or Thy with the four carbons of a 5' Cyt. However, using the same wavelength of excitation in the UVB, 6-4PPs are induced only at 15–30% the rate of CPDs [81]. Using fluorescently labeled monoclonal antibodies against CPD and a calibration with a radioimmunoassay (RIA) [82], it was shown that a UVB dose of 300 Jm^{-2} is able to induce several hundred thousands of CPDs per genome per cell [83]. Both induction of CPDs and repair of these lesions via nucleotide-excision repair (NER) are UV-dose dependent. Increasing both the UVB dose and the amount of premutagenic CPDs leads to a increase of the time constant for NER to remove CDPs [83]. Furthermore, deficiencies in NER of CPDs have been linked with increased risk of cutaneous malignant melanoma and non-melanoma skin cancers [84–86].

When CPDs are not repaired, these DNA lesions can lead to mutations in the DNA sequence. Mutations are in the form of C→T and CC→TT transitions, known as "UV-signature mutations" [87–90]. These mutations have long been believed to be a specific signature for UVB-radiation. However, recent work suggests that UV-A also induces CPDs that lead to UV-signature mutations [91–93]. This view is supported by results showing that UV-A induces mainly CPDs in human skin [94]. A so called "A-rule" has been proposed to explain how these signature mutations arise [95]. According to the A-rule, DNA polymerase (pol η) inserts, in a default-mechanism, adenine (A) residues,opposite to those lesions it cannot interpret. A mutation is then created upon DNA replication of the strand containing base-pair changes. At a CC cyclobutane dimer, therefore, a CC → TT transition occurs because two A-residues are placed opposite the dimer by default, in place of two guanine (G)-residues. A similar default mechanism for 6–4 PPs might be responsible for C→T transitions [95]. Recent findings show that defects in efficiency of translesion polymerase η (despite other polymerases) seem to play an important role in UV-induced mutagenesis [96, 97].

UV-signature mutations have been detected in a number of tumor suppressor genes and oncogenes (including, e.g., *patched, p16, ras* and *p53*) in human SCC, BCC, and malignant melanoma [95]. Because the important biological function of p53 results from transcriptional activation of a large number of genes involved in fundamental cellular processes like cell cycle control, apoptosis, DNA replication, repair, genome instability, and senescence, it is not surprising that genetic alterations of the p53 gene have most frequently been found in human tumors [98]: especially in skin cancers like SCC, BCC, and precancerous actinic keratoses [99–103]. Convincing models for the initial steps of UV-carcinogenesis, especially for SCC, already exist [104, 105] based on findings that p53 mutations in non-melanoma skin cancers are detected at higher frequency (50–90%) than those in internal malignancy, and that the predominant alterations are

C→T and CC→TT transitions at dipyrimidine sites [103]. Very recent investigations, exploring the melanoma genome, furthermore show that UV-induced signature mutations play the primary role in melanoma induction in humans [106].

Etiology of Skin Cancer In recent years, a huge amount of information has been obtained in the fields of genetics, molecular pathways, and cellular changes, which are important players in skin cancer induction, promotion, progression, and metastasis. Excellent reviews are now available [107–112]. Very briefly, there is convincing evidence that the BCC etiology is highly dependent on dysregulation of the hedgehog signaling pathway, whereas for the SCC etiology, p53-regulated pathways are of outstanding importance. For malignant melanoma, at least three molecular pathways have been found to be nearly invariably disregulated in melanocytic tumors, including the RAS-RAF-MEK-ERK pathway (through mutation of BRAF, NRAS or KIT), the p16 INK4A-CDK4-RB pathway (through mutation of INK4A or CDK4), and the ARF-p53 pathway (through mutation of ARF or TP53). Less frequently targeted pathways include the PI3K-AKT pathway (through mutation of NRAS, PTEN, or PIK3CA) and the canonical Wnt signaling pathway (through mutation of CTNNB1 or APC) [113].

It is to be expected that future research dealing with biological markers will give further insight into the etiology of skin cancer. Furthermore, very recent findings in the field of stem-cell research very clearly show that epidermal stem cells and their regulation on the genetic and epigenetic levels are the main cell targets involved in skin carcinogenesis [113–120]. Investigating the genetic and epigenetic regulation of (cancer-) stem cell fate, therefore, will enduringly increase knowledge about the etiology, as well as about (bio-) markers indicative for progression, staging, and metastasis of skin cancers.

Immunosuppression

It is now generally accepted that chronic and/or intermittent UV-exposure from the sun or from artificial sources (e.g., sunbeds) can initiate and promote skin cancer development through two major mechanisms: (1) induction of UV-dependent mutations; and (2) UV-induced immunosuppression, which might impair recognition of, e.g., UV-induced tumors (as an antigen source) by immunocompetent cells in the skin [121]. The "skin immune system" (SIS) is composed of several different cell types: keratinocytes (KC), melanocytes (MC), fibroblasts, monocytes, epidermal homing T cells, dermal macrophages, and Langerhans cells. These cells interact in a complex network via a number of soluble mediators like cytokines, interleukines, and prostaglandins and build up immune response and immunosurveillance of the skin [122].

UV-induced immunosuppression has been demonstrated initially by in vivo experiments with mice. These studies were able to show that (UV-induced) skin tumors are not rejected when transplanted to previously UV-irradiated mice. Later on, it was shown that UV-radiation mostly impaired the cellular immune response, leaving humoral immunological pathways almost untouched. The cell-mediated immune response was then studied in a large number of investigations with contact or delayed hypersensitivity reactions (CHS or DTH) as a biological endpoint in human skin [122, 123]. These investigations show that antigenes applied to the skin are taken up by antigen presenting cells (APC), where they are processed and finally presented to T lymphocytes to induce the complex immune response to eliminate the antigen.

UV-induced immunosuppression works both locally and systemically. Locally, the site of hapten application corresponds to the UV-irradiated area of skin. Systemic immunosuppression, on the other hand, induces the effect far away from hapten application. Local immunosuppression is mediated by direct UV-induced alterations in APC function, whereas systemic immunosuppresion needs mediators like e.g., Interleukin-1, 10, 12, tumor necrosis factor (TNF-α) or tumor-growth factor β (TGF-β). Furthermore, dose-rate effects of UV-irradiation seem to have an influence on whether immunosuppresion is induced locally or systemically [124].

UV-radiation needs photoreceptors that are able to "translate" UV-interaction into immunomodulatory effects at the cellular level. According to absorption- (and action-) spectra, the most important chromophores involved in immunosuppression are: urocanic acid (UCA) and DNA [123].

UCA is one of the major UV absorbing components in the *stratum corneum* of human skin and undergoes *trans* to *cis* isomerization after UVB irradiation [125]. Cis-UCA then modulates the action of several cytokines, including TNF-α, IL-6, IL-8, IL-12, and others [126, 127], in this way influencing the complex reaction pathways of SIS. It is well accepted now that UV-B-radiation-induced UCA changes, which are involved in immunosuppressive pathways, both work locally and systemically in mice and humans [122, 125, 128], although there exists some evidence that UV-induced production of cis-UCA might be insufficient to suppress CHS [129].

Another, possibly more important molecular target to interact with UV-radiation and to induce immunosuppresion, is DNA [130]. DNA is able to absorb UV-B irradiation directly, which creates cyclobutane pyrimidine dimers (CPD) and (with lower yield) 6–4 photoproducts [90]. These are known to be pre-cancerogenic DNA lesions, giving rise to UV-signature mutations, prominantely involved in the skin cancer etiology. However, these lesions (if not repaired) are also responsible for direct activation of genes involved in immune reactions [131]. CPD play an important role in immunosuppression through alterations of APC function [132], cytokine production, e.g., IL-10, and inhibition of transcription factors [133]. An increase of enzymatic repair activity for CPDs (via support of repair enzymes T4 endonuclease V) restores CHS and DTH response after UV-irradiation [134].

There is convincing evidence that cis-UCA and CPDs mediate their immunosuppressive properties through the impairment of immunocompetent cells populations like APCs, especially Langehans cells [135, 136]. One of the major actions of UV radiation on LC is that it makes them unable to prime Th1 lymphocytes, therefore inducing some tolerance against antigenes [137]. This leads to the hypothesis that UV induced cytokine might affect the critical balance between Th1 and Th2 cells in favor of an (immunosuppressive) Th2 response [138, 139]. There is a convergence of evidence now supporting this hypothesis.

Most of the immunosuppressive effects of UV-radiation have been documented after experimental UV-B irradiation on subjects [122]. However, there is increasing evidence that UVA-radiation (315–400 nm) might also be capable of inducing immunosuppression in human skin [140–143]. From a mechanistic point of view, this seems reasonable because it has recently been shown that UVA (apart from other premutagenic DNA-lesions) predominantly induces CPDs [94] (known to be involved in immunosuppression, see above) in human skin.

Skin Treatments

During the past decade, UV-radiation has been used extensively to cure certain types of skin diseases, especially psoriasis, which is shortly discussed here as an example.

Psoriasis is one of the most frequent inflammatory skin disorders. Its prevalence is estimated to be 2% in the Caucasian population, and it may develop at any age [144]. Immunological mechanisms play an important role, and it is now recognized that psoriasis is the most important T-cell mediated inflammatory disease in humans [145]. The primary immune defect in psoriasis appears to be an increase in cell signaling via chemokines and cytokines that act on upregulation of gene expression and cause hyperproliferation of keratinocytes [146]. There exists, however, strong evidence for an equally important role of polygenetic inheritance in complex genetics of psoriasis [147]. At least eight genetic loci (PSORS1–PSORS8) have been identified so far [147, 148].

Classic psoriarsis treatments use UV radiation. Broadband UV-B, narrowband UV-B (311 nm), as well as psoralen plus UV-A (PUVA) treatments have been used in the past [149]. Among other things, UV radiation reduces the number of antigen presenting cells and affects cell signaling pathways responsible for a decrease of hyperproliferating keratinocytes. UV-B-radiation seems to be less effective than PUVA-therapy. However, the latter carries an elevated risk of skin cancer induction [150–153]. For instance, high-dose PUVA patients (with more than 337 PUVA treatments) carry a 68-fold increase in overall risk of SCC (fourfold increased risk of BCC) [154].

Eye Damage

With the exception of snow- and ice-covered surfaces, most surfaces have a very low UV reflectivity. However, over ice- or snow-covered areas, reflections can directly

increase the eye exposure. In some case, this natural reflectance can be as high as 100% [155]. These enhanced radiation fields can contribute to eye damage. Some impacts on the eye are described below. For more details, see [7].

Photoconjunctivitis

Photoconjunctivitis is an inflammation of the conjunctiva of the eye caused by UV radiation. The action spectrum is similar to DNA damaging radiation. The threshold irradiation for photoconjunctivitis is 50 J m^{-2} [156].

Photokeratitis

Photokeratitis is an inflammation of the cornea's epithelial layer caused by UV radiation. The action spectrum is again similar to DNA damaging radiation. The threshold irradiation is 50 J m^{-2} [156].

Cataract

Cataracts are irreversible turbidities of the eye that can be caused by infrared (IR) or UV radiation. IR cataracts are caused by direct absorption of IR radiation or, indirectly, by heat transfer from the iris to the lens. They are usually caused by long-term (many years) exposure to large infrared sources and are therefore rare as a result of sun exposure only. UV cataracts are quite common. However, there is no known action spectrum for IR or UV cataracts [156].

Visible Radiation and Health Effects

Circadian Effects

It is well known that visible radiation has an impact on human health by affecting the eyes. The major task for the eyes is to gather and further process incoming visible radiation. Basically, the eye acts like a camera. In this "picture," the retina is the film or, more appropriately, the sensitive array that converts incoming photons to electrical signals that are further processed in the brain. For 150 years, it has been known that there are two types of sensors in the retina: the rods and the cones. There is some evidence that visual perception has an indirect impact on human health through psychological effects. However, this is not discussed further here.

In recent years, another photoreceptor, called melanopsin, has been found. It is likely that this photoreceptor has been developed early in the evolution of man. Melanopsin has a lower sensitivity and a coarser spatial resolution compared to the rods and cones. It is "designed" to help synchronizing the inner clock with the solar day.

The inner clock is thought to be essential to human health. The concentrations of many hormones are regulated by the inner clock, and it is known that a long-term disturbance of the inner clock has negative impact on humans [157]. For example, it is known that night-shift workers have a higher incidence of cancer.

The suppression of melatonin is closely linked with melanopsin concentration. The known action spectrum of melatonin suppression has its maximum in the blue part of the spectrum, at about 460 nm and almost no sensitivity in the red part [156]. Since the spectral transmission of the aging human eye progressively shifts toward longer wavelengths, it is assumed that elderly people have a reduced ability to synchronize the inner clock from blue light.

Since the solar spectrum changes appreciably during the day (see chapter ?) – certainly much more than the visual impression, which is regulated by the brain to recognize objects regardless of the incoming solar spectrum – it can be assumed that the red-shift of the solar spectrum during mornings and evenings may also have an impact on the melatonin suppression as well. This is an example of impacts of the solar spectrum on human health that is being understood, and that should be regarded when artificial lighting is used.

Damage of the Retina

Radiation (including infrared) that is absorbed by the retina can cause thermal damage. UV does not play a role in this case because it has a relatively low thermal contribution and is mostly absorbed before it reaches the retina. What is relevant to the damage of the retina is not the irradiance but its thermal impact [156].

Infrared Effects

For a long time, infrared radiation was considered as biologically irrelevant for human health. Consequently,

the study of the impact of infrared radiation only began relatively recently [158]. Infrared radiation produces a high concentration of reactive oxygen species (ROS), i.e., free radicals, that can damage the skin. It was shown that the generation of free radicals depends not only on the incident irradiance but also on the temperature of the skin, which is increased by infrared radiation [159]. A doubling of the irradiance from 400 to 800 W/m^2 can increase the temperature by ~10°C. Such a temperature change enables biochemical reactions in the skin. There are nonlinear dose-effect relationships. The production of free radicals starts at about 37°C and becomes much stronger at about 41°C. However, further increase in temperature to 43°C causes little additional damage. At low latitude sites or in a likely warmer climate of the near future, increased infrared irradiation will lead to an increased formation of ROS, which is potentially dangerous for human health [159]. As a consequence, infrared protection may be beneficial, in as much as the threshold skin temperature of 41°C is not reached. For example, at a latitude of 43.4° N (corresponding to Monaco), these experiments value can be reached after only 20 min of sun exposure. However, these experiments were made with artificial light (Sullux 500 W), which emits a nearly continuous spectrum, whereas the solar irradiance has absorption bands, especially from water vapor. It is not known to what extent such effects can play a role when evaluating the potential danger of infrared radiation for humans. In addition, the spectral transmittance of infrared radiation must be considered. In the near-infrared (IR-A), the spectral transmittance of the skin varies between 2% and 10%. The maximum transmittance is reached at about 1,150 nm.

Several other studies of infrared affects have been undertaken [160, 161] Schieke 2002 [155]; Jantschitsch 2009 [163]. They use a special infrared light source (called "hydrasun") that includes a water filter to minimize heating from long-wave radiation. Experiments with this source show that there is a time- and dose-dependent metalloproteinase-1 (MMP-1) that leads to increased skin aging [162], similar to that from UV exposure. The necessary dose may be reached after 2.5 h of exposure at midlatitudes in summer. However, another study [160] found that even with a high irradiance (380 W/cm^2), there is no systematic induction of MMP-1, which is clearly in contradiction with the findings in [162]. Another study [161] found that, without increased temperature, there is a protection of infrared radiation to UV exposure – a result confirmed by another study [163].

In summary: there are clear indications for effects of infrared radiation for human health, but the complete process is far from being well understood.

Effects for Which the Spectral Responsivity Is Not Yet Known

Depression

Depression can occur as a result of a lack of light in winter. This is often described as seasonal affective disorder (SAD), also known as winter depression. The U.S. national library of medicine notes that some people experience a serious mood change when the seasons change. They may sleep too much, have little energy, and crave sweets and starchy foods. They may also feel depressed. Though symptoms can be severe, they usually clear up naturally. It has been estimated that 1.5–9% of adults in the U.S. experience SAD [164]. There are many different treatments for classic (*winter*-based) SAD, usually using artificial bright lights, or a temporary stay at a southern, sunny location. However, the spectral sensitivity of SAD is not known yet. It may be cured just by exposing the eyes with bright light, but it may be also connected to a deficiency in vitamin D.

Human Behavior in Response to Solar Radiation

Humans change their behavior in response to changes in solar radiation. Possible reactions include: avoiding too intense solar irradiation by seeking shadow, or seeking high level of solar irradiance for cultural or cosmetic reasons. As a consequence, human health is not only influenced by changes in solar irradiation (geographically, daily, seasonally), but to a large extent also by human behavior. Of course, such reactions depend on many factors, both socioeconomic and individual, and it is therefore hard to give general statements on the advantages or disadvantages of changes induced by human behavior in response to solar radiation.

Future Directions

The descriptions above clearly show that solar radiation has both positive and negative effects on human health. Positive effects are the synchronization of the inner clock by natural sunlight and avoidance of winter depression, which affects many people at higher latitudes. Another positive effect is the vitamin D production, for which an overdose by natural sunlight is not known. There is clear evidence that high vitamin D levels are very beneficial to humans. The list of the resulting positive effects has increased considerably in recent years.

On the other hand, there is also clear evidence that UV radiation is mainly responsible for skin cancer, for which the incidence rates are rapidly increasing, probably as a result of changed behavior. Also, negative effects of UV radiation on the eyes are well known. Strong indications of negative impacts of infrared radiation have been found recently.

The positive aspects just mentioned have already led to changes in the "sun-smart" recommendations given by some national cancer agencies. In the past, the most frequent recommendation may have been along the lines "avoid the sun as much as possible." This is now altered to "avoid being sunburnt." Other suggestions are "avoid the sun in summer, seek it in winter." Despite the great number of studies and publications on these topics, there seems to be still insufficient scientific knowledge to convey simple messages to the public about the optimum solar exposure. It is clear that overexposure leads to severe negative effects, whereas underexposure has a negative impact on human health. It is concluded that more research is needed to assess under which conditions either overexposure or underexposure occur and must be considered. This is a rather difficult question for which simple answers are not to be expected soon due to the complexity of human health and of varying physical and meteorological conditions [165]. In addition, the relevant quantity to consider in vitamin D studies is not the irradiance on a horizontal surface but the actual exposure, which requires knowledge of the spectral radiance. This quantity, however, is far from being as well known as the widely used irradiance. More studies are required since the solar radiation regime is expected to be modified as a consequence of climate change.

Glossary

Aerosol optical depth A dimensionless parameter for the extinction of solar radiation by scattering and absorption by aerosol particles between the point of observation and the top of the atmosphere.

Air mass The length of the path from an observer's location to the top of the atmosphere, which passes through the center of the sun, relative to the zenith (perpendicular to the local horizontal = air mass 1).

Broadband radiation Photons in a wide electromagnetic spectral wavelength range, typically several hundred nanometers (nm) wide.

Diffuse hemispherical radiation Photons scattered in the atmosphere, excluding those from the solar disk, arriving on a horizontal surface originating from the 2π steradian hemisphere of the sky dome.

Direct normal radiation Nearly parallel rays of photons arriving on a surface perpendicular to the line from the observer to the center of the solar disk originating from within the 0.5° solid angle centered on the solar disk. Experimentally, this also includes additional sky radiation within 2.5°–3° of the center of the solar disk.

Extinction Gradual loss of amplitude in a signal propagating though an absorbing or scattering medium.

Extraterrestrial solar radiation Direct normal radiation at the top of the Earth's atmosphere. Acronym: ETR.

Global hemispherical radiation The combination of photons from the sky dome and solar disk (diffuse hemispherical and projection of the direct normal radiation) received on a horizontal surface.

Incidence angle The angle between the center of the solar disk and the foot of the normal (perpendicular) of a receiving surface.

Pyranometer A radiometer with a 2π steradian (hemispherical) field of view used to measure global hemispherical or diffuse hemispherical radiation.

Pyrheliometer A radiometer with a restricted field of view (typically 5°–6°) used to measure direct normal radiation.

Responsivity The ratio of the output signal of a radiometer to the optical power intercepted by the sensor.

Solar radiation Electromagnetic emissions from the sun between at least 250 and 2,500 nm.

Zenith angle The angle between the local vertical and the center of the solar disk; complement of the solar elevation angle (angle from the center of the solar disk to the horizon).

Definition of the Subject and Its Importance

Present-day concerns of looming energy shortages and drastic climate change resulting from human activities have stimulated deployment of renewable energy systems, including systems to convert solar energy directly into heat or electricity and to substitute sunlight for artificial light.

Solar radiation provides the energy driving the ecosystems and climate of planet Earth. This radiation spans the electromagnetic spectrum from the highly energetic X-ray region through the ultraviolet, visible, and infrared to the far infrared and radio regions. The radiation interacts with the Earth's electromagnetic and atmospheric envelope, resulting in large variations in

the magnitude of solar radiation available for conversion into other forms of useful energy. Most conversion systems utilize only part of the solar spectrum. For daylighting, the energy in the human visual response range (wavelengths of 380–850 nm) is important. Crystal silicon photovoltaic cells convert radiation from 350 to 1,100 nm, and plants use photosynthetically active radiation between 400 and 700 nm. Efficiency and performance of these systems is usually based on the total solar broadband radiation measured between 250 and at least 2,500 nm.

Specialized instruments have been developed to quantify the available broadband solar resource and spectral regions utilized by each technology. The cost and labor-intensive nature of solar radiation measurements has stimulated efforts to develop empirical and theoretical mathematical models of broadband and spectral solar radiation at the Earth's surface. A brief historical introduction is followed by current information on broadband solar radiation components, instrumentation, and modeling.

Introduction

The sun is a star, with radiant emittance of 2.009×10^7 watts per square meter per steradian ($W/m^2/sr$), or 2.845×10^{26} W in total. The Earth's elliptical orbit has an eccentricity of 0.0167 (1.4710×10^6 km at perihelion, 1.5210×10^6 km at aphelion). At the mean Earth–sun distance, the sun subtends a solid angle of 9.24 mrad, or 0.529°. Thus, the sun is not truly a point source, and the rays from the sun are not truly parallel but diverge into a cone with a nominal cone angle of 0.529° [1]. At the mean distance of the Earth from the sun (1.495979×10^6 km), the solar radiation reaching the top of the Earth's atmosphere is 1366.1 $W/m^2 \pm 7.0$ W/m^2 [2]. A very slender cone, or beam, of photons, the direct normal radiation (because it is typically measured with a sensor surface perpendicular to the beam), or direct beam, is intercepted by the Earth and passes through the atmosphere. Photons scattered by molecules and particles in the atmosphere that are not further absorbed contribute to uncollimated diffuse irradiance of the sky dome. The combination of direct normal and diffuse sky radiation constitutes the total solar radiation (usually total hemispherical or "global" total) available from the sky dome.

Figure 1 shows typical spectral power distributions, or magnitude of solar energy as a function of wavelength, over the "optical" part of the spectrum. The Earth's 100-km thick atmosphere filters solar radiation in a manner that protects and promotes life, provides the energy to drive the Earth's weather and climate, and affects the quality and quantity of resources available for solar energy conversion systems. The bars at the top of Fig. 1 show the portions of the spectral distribution utilized by various natural and manmade energy conversion systems. The extraterrestrial curve in Fig. 1 is the radiation reaching the top of the Earth's atmosphere. The other curves represent the effects of the atmosphere on the extraterrestrial energy as it propagates through the atmosphere. Broadband terrestrial solar radiation for solar renewable energy applications is represented by the integrated or total energy bounded by the direct, total, and diffuse curves represented in Fig. 1. Energy between the wavelengths of 280 and 4,000 nm, the so-called shortwave or optical radiation, is the primary subject of this article. (Note that, at the Earth's surface, the energy received between 2,500 and 4,000 nm is only about 3% of the total.) Shortwave radiation is relevant to photoconversion systems, such as photovoltaic (PV) and photo-thermal systems, daylighting, and photosynthesis by plants. Longwave radiation, 4,000–50,000 nm or 4–50 μm, has some application in solar thermal energy systems but is primarily important in climate change and infrared thermal studies. Some radiation is reflected back into space or away from the ground by the atmosphere, clouds, or ground. Figure 2 shows these processes schematically.

Solar Radiation Components

The combination of direct-beam radiation and diffuse radiation on a horizontal surface is the total (hemispherical), often called the global horizontal irradiance. Daily, the sun moves through a range of elevation angles from 0° at sunup, to a maximum at solar noon, to 0° at sunset. Thus, for a horizontal surface, the direct beam is usually not perpendicular to the horizontal surface, but incident at some angle i. The angle i is referred to as the zenith angle, Z (the angle between the local vertical and the center of the solar disk) for a horizontal surface. The direct-beam flux

Representative distributions of power as a function of wavelength for solar energy at the top of the atmosphere (extraterrestrial), solar beam radiation, diffuse sky radiation, and total radiation on a horizontal surface for clear sky conditions. *Bars* show regions of energy utilization by conversion systems

Solar Radiation for Solar Energy Utilization. Figure 2

Scattering of the direct-beam photons from the sun by the atmosphere produces diffuse sky irradiance

density multiplied by the cosine of the incidence or zenith angle produces the flux density on a surface (Lambert's cosine law).

The total irradiance on a horizontal surface, G, is equal to the (direct beam, B) $\times \cos(Z)$ plus the diffuse irradiance (F) from the rest of the sky impinging on the horizontal surface, as in Eq. 1.

$$G = B\cos(Z) + F \tag{1}$$

The rest of this article is devoted to the calibration, measurement, and modeling of the global, direct, and diffuse terrestrial solar radiation components for renewable energy applications.

Brief History of Solar Radiation Instrumentation

Excellent detailed reviews of the history of solar research are given in Whipple [3], Coulson [4], and Hufbauer [5]. Ancient civilizations fully appreciated the life-supporting properties of the sun and the annual solar cycle [6, 7]. The earliest recorded speculations on the physics of the sun in Western natural philosophy are those of the Greeks, beginning about 340 BC with Aristotle, Aristarchus (270 BC), Apollonius (220 BC), Hipparchus (140 BC), and Ptolemy (AD 140). The first to publish a non-Aristotelian view of the solar system was Copernicus (d.1543), who greatly influenced near contemporaries, especially Galileo (d.1642) and Kepler (d.1630). With the advent of the telescope, Galileo discovered sunspots (1610) and the solar rotation. In the late seventeenth century, Flamsteed, Cassini, Halley, Newton, and others devoted efforts to determining the sun's mass, size, and distance as well as developing the now familiar model of the solar system. Sir Isaac Newton (1642–1727) performed scientific study of light from the sun with his well-known experiments involving prisms in a darkened room. Newton described sunlight as composed of "all colors" of light. In 1800, William Herschel (d.1822) used thermometers mounted just beyond the red end of the simple Newtonian optical spectrum to measure infrared (IR) or heat energy in the solar spectrum. Similarly, Johann Wilhelm Ritter detected ultraviolet radiation beyond the blue end of the Newtonian spectrum with silver iodide salts in 1802.

While Hershel attempted to estimate the solar "heat" output, in 1837 Claude Pouillet made the first estimate of the "solar constant" as the amount of heat from the sun impinging on a square centimeter of the top of the Earth's atmosphere. He coined the term "pyrheliometer" and derived a value of 1.76 cal/cm^2/min (1,227 W/m^2), which is within 10% of the presently accepted value.

In the first half of the nineteenth century, Fraunhofer (d.1826) identified more than 500 dark lines in the solar spectrum. By 1823, William Herschel's son, John Herschel, proposed that these lines were associated with absorption by constituents of the solar atmosphere. In 1859, the chemists Gustav Kirchoff (d.1887) and Robert Bunsen (d. 1899) proved John Herschel's absorption hypothesis by associating the laboratory emission spectra and the solar absorption spectra of several key elements, especially sodium.

Samuel Pierpont Langley (d. 1906) spent much of the period from 1870 to 1900 attempting to determine the total spectral energy content of the sun with his bolometers (based on the change in resistance of material with temperature). Langley's solar spectrum, published in 1883, is shown in Fig. 3 (compare with Fig. 1) [8].

Table 1 presents a summarized timeline of the development of solar radiation measurement instrumentation.

Figure 4a–i show the evolution and variety of solar radiometers for measuring global hemispherical, direct normal, and diffuse sky radiation.

The Solar Radiation Measurement Scale: World Radiation Reference

In 1970, Kendall [19], and later Willson [20], at the Jet Propulsion Laboratory developed electrical compensation radiometers (see Fig. 5) utilizing conical blackened-silver cavities with thermojunctions that could be calibrated using electrical heating in place of heating from solar radiation.

These and instruments of similar design by Crommelynck [21], Brusa and Fröhlich [22], and Hickey [23, 24] became the standard for the World Radiometric Reference (WRR) established by the World Meteorological Organization/World Radiation Center (WMO/WRC) and now in use [25]. Figure 6 shows the relationship of a group of absolute cavity radiometers to the definition of WRR, determined by

Solar Radiation for Solar Energy Utilization. Figure 3
Langley's 1883 solar spectral distribution

periodic international intercomparisons. Figure 7 is a photograph of the instruments that constitute the World Standard Group (WSG), which is used to define the WRR. As mentioned above, the WRR is the measurement standard for the International System, or *Systeme International* (SI), unit of solar irradiance [26]. The WRR was introduced to ensure homogeneity of solar radiation measurements and has been in use since 1980 [27]. There have been laboratory comparisons between WMO/WRC cavity radiometers and cryogenic absolute cavity radiometer, the SI standard for realizing the radiometric scale for laboratory measurements. The comparison showed that the PMO6 serial numbers −9 and −11 cavity radiometers (corrected to WRR) reproduced the SI laboratory irradiance scale to within 0.05% [28].

Calibrations and Traceability

The traceability of measurements requires an unbroken chain of comparisons with defined uncertainties to stated references. The traceability of the WSG cavity radiometers to SI units is with respect to electrical (volt, ohm, and ampere) and physical-dimensional (length, area) standards maintained by national standardizing laboratories. Detailed characterization of the aperture area, absorption of the cavity, and electrical components of the measurement system substantiates the "absolute" nature of the WSG measurements.

Every 5 years, WMO sponsors the International Pyrheliometer Comparisons (IPC). The WMO representatives of any country are invited to bring their reference solar radiometers to the PMOD/WRC institute in Davos, Switzerland to compare them with the WSG and derive a WRR correction factor [29]. The test radiometers are compared with the WSG using a rigorous data collection and processing protocol documented in Reda [30]. Periodically, regional and local intercomparisons are conducted using at least one, and preferably more, reference cavity pyrheliometer. Radiometers participating in such local intercomparisons are assigned suitable WRR correction factors. Radiometers under calibration include instruments behind quartz or Schott WG295 glass domes (pyranometers) and Corning 7250 quartz Infrasil windows (pyrheliometers) that transmit shortwave radiation over the spectral intervals 295–2,800 nm and 200–4,000 nm, respectively. However, as the reference absolute cavity radiometers providing the reference direct-beam irradiance have no windows, effectively measuring the total beam solar radiation over all possible wavelengths, the spectral cutoff of the domes and windows is effectively "calibrated out" in the comparison process.

Figure 8 shows the traceability path for working field radiometers to WRR through the WSG. Increasing uncertainty at each level is for field radiometer calibrations including transfer process and test radiometer stability.

Pyrheliometer Calibration

Pyrheliometer responsivities (Rs, or output signal per stimulus unit) are derived by direct comparisons with reference cavity pyrheliometers traceable to WRR. The approach is much like the transfer of WRR between cavity radiometers. The ratio of test pyrheliometer signals to the reference irradiance from the reference cavity pyrheliometer is computed over the course of

a clear day or several clear days. Figure 9 shows typical data for such a calibration. National [31] and international [32] standards documents describe the procedures for calibration of field pyrheliometers from primary (absolute cavity) pyrheliometers and reference pyrheliometers.

The shape of the response function for a field pyrheliometer seen in Fig. 9 is of concern, as the distribution of the responsivities is not random but biased differently in the morning and afternoon. The cause for this bias is a current topic of research. Possible explanations are the different fields of view of the reference (5°) and test (5.7°) pyrheliometers, environmental influences (ambient temperature, wind speed, and direction), and test instrument design (thermal gradients between detector and reference thermocouples).

Pyranometer calibration

Pyranometer responsivities may be derived from one of two techniques. The first is a "shade/unshade" technique. Responsivity for a diffuse-measuring reference pyranometer, shown as Rsd, is derived in a shade/unshade calibration using the formula $\mathrm{Rsd} = (U - S)/[B\cos(Z)]$, where U and S are the unshaded and shaded output voltages from the sensor, Z is the zenith angle, and B is measured by a reference pyrheliometer. Procedures for this calibration are described in the American Society for Testing and Materials Standard G167 [33] and international standard ISO 9060 [34].

Significant issues affect the apparently simple shade/unshade calibration. The pyranometer under test has several time constants, caused by differing heating and cooling rates of the domes and detectors as the shade is imposed and removed. In contrast, the diffuse sky radiation, particularly the IR radiation temperature, remains relatively constant. Therefore, the net IR exchange between the instrument and the sky is different in the shade and unshade condition, which leads to changing thermal offsets in the detector, discussed below. Variations in the direct-beam radiation over the shade and unshade periods (at the beginning and end of the shade period) can lead to errors. A modification to the standard shade/unshade pyranometer calibration that determines an average responsivity at 45° zenith angle for three instrument azimuth angles provides an integration over geometric response variations [35, 36].

With this modified shade/unshade technique, clear-sky diffuse irradiance can be measured with an uncertainty of ±(3% of reading + 1.0 W/m^2). For typical clear-sky calibration conditions, the diffuse irradiance is on the order of 10% of the total global hemispherical irradiance. This means that the uncertainty in the total global reference irradiance because of uncertainty in the diffuse reference irradiance is on the order of ±(0.3% of the total reference irradiance, +0.3 W/m^2).

For a "component summation" calibration of a pyranometer, the reference global irradiance (G_r) is derived from an absolute cavity radiometer beam measurement (B) and shaded pyranometer (diffuse) measurement (F) using $G_r = B\cos(Z) + F$, shown symbolically in Fig. 10. The ratio of the test pyranometer signal to the reference global irradiance is then the responsivity, or calibration value, for the pyranometer.

This technique requires a shade/unshade calibrated pyranometer to measure the "reference diffuse" irradiance, F, during the calibration. The instantaneous voltage signals of the test radiometers are divided by the reference global irradiance G_r to generate instantaneous responsivities typically in units of μV/W/m^2. Figure 11 shows a typical plot of responsivity versus zenith angle throughout a day. As with the pyrheliometer example discussed above, the response of the pyranometer is not constant with respect to the solar incidence angle. In the band of incidence angles from 0° (normal incidence) to 60° (solar elevation of 30°), responsivity may vary by 5% or more. Every individual

Solar Radiation for Solar Energy Utilization. Figure 4
(**a**) Abbott Silver disk pyrheliometer [10], (**b**) Ångström's pyrheliometer [12], (**c**) Eppley Model 50 pyranometer, (**d**) Schenk Star pyranometer [17], (**e**) tracking shading disk and shaded pyranometer, (**f**) Eppley Model PSP pyranometer, (**g**) Eppley normal incidence pyrheliometer on tracker, (**h**) Li-Cor Inc. silicon photodiode pyranometer, and (**i**) sketch of rotating shadow band radiometer with silicon photodiode detector

pyranometer will have a distinct, unique, individual "signature," even for a given model designation. Similar signatures are obtained from pyranometers calibrated if the shade/unshade techniques are used over a large range of zenith angles. Thus, it is important that calibration methods, selection criteria for a responsivity (or calibration factor, Cf, equal to 1/Rs), and range of Rs (or Cf) be described to adequately characterize the uncertainty in solar radiation measured with the pyranometer.

Uncertainty Analysis

All measurements only approximate the quantity being measured and are incomplete without a quantitative uncertainty. The Guide to Measurement Uncertainty (GUM) of the International Bureau of Weights and Measures (BIPM) [37] is the accepted international guide for conducting measurement uncertainty analysis. The GUM defines Type A uncertainty values as derived from statistical methods and Type B sources

Solar Radiation for Solar Energy Utilization. Figure 5
Kendall's design [21] for an absolute cavity radiometer receiver. Electrical current through the heater winding set to match solar heating of the cavity

as evaluated by "other means," such as scientific judgment, experience, specifications, comparisons, or calibration data.

Every element of a measurement system contributes elements of uncertainty. When a result, R, is functionally dependent on several $i=1,...,n$ variables, x_i, the familiar propagation of error formula $U^2 = \sum_i (\partial_{Xi} R \cdot e_{Xi})^2$ is used, where U is the uncertainty in the resultant, e_{xi} is the estimated uncertainty in variable x_i, and $\partial_{xi} R$ is the partial derivative of the response R with respect to variable x_i, called the sensitivity function for variable x_i.

Previously, uncertainty analysis treated sources of uncertainty in terms of "random" and "bias" types. Total uncertainty, U, was computed from: $U^2 = \sqrt{[(\text{Bias})^2 + (2^*\text{Random})^2}$ [38]. The factor of 2 was applied to the "random" or statistical uncertainty component because this component usually represented a standard deviation. This method was considered to report uncertainty with a 95% "confidence interval." The resulting uncertainty in calibration of pyranometer responsivity and field measurements was 2.4% and 5%, respectively. The GUM replaces the factor of 2 with a "coverage factor," k and $U^2 = \sqrt{[(\text{Type B})^2 + (k^* \text{ Type A})^2]}$. For small ($n<20$) samples, from a Gaussian distribution of measurements, k may be selected from the t-distribution [37, 39]. U is the "expanded uncertainty," and k is usually in the range of 2–3, for confidence intervals of 95% and 99%, respectively. In the following, the GUM approach is followed in an uncertainty analysis.

Radiometer Calibration Sources of Uncertainty

Several types of detectors, including silicon cells and thermal detectors such as resistance thermometers and thermopiles, are used for pyrheliometer and pyranometer instruments.

Solar Radiation for Solar Energy Utilization. Figure 6 Relationship of various absolute cavity radiometers to the WRR scale defined by the present WSG

All-Black Detector Thermal Offsets Studies of solar radiation instrumentation in climate research, such as those by the World Climate Change Research Program Baseline Surface Radiation Network (BSRN) participants [40] and others [41–44], have characterized thermal "zero offsets" in thermopile pyranometers with all-black sensors measuring diffuse radiation. The offsets produce negative engineering data at night and clear-sky diffuse irradiances lower than what pure Rayleigh scattering theory predicts. Thermal offsets occur because the cold junctions of the all-black detector thermopile are in a different thermal environment (inside the radiometer) than the exposed absorbing hot junctions. Empirical tests [43] show that thermal infrared exchange among the warm sensors, domes, and cold sky generates these offsets. Some have proposed that shade/unshade calibrations result in "cancellation" of the thermal offsets in the shaded and unshaded state [45]. For black-and-white sensors, the reference and absorbing thermopile junctions are in a similar thermal environment when shaded and unshaded. These radiometers have lower (~1–2 W/m^2) offsets and should produce more accurate diffuse sky measurements. Experiments have been conducted [43–45] that characterized thermal "zero offset" signals in thermopile pyranometers with all-black sensors. Silicon photodiode instruments do not have thermal offsets, though they do have temperature coefficient of responsivity typical of silicon – about 0.15%/°C.

Solar Radiation for Solar Energy Utilization. Figure 7 Six absolute cavity radiometers of various designs constitute the WSG of pyrheliometers that define the solar radiometric scale, the WRR (WRC, Davos, Switzerland)

Spectral Effects There is spectral effect on the shade/unshade calibration. The diffuse sky radiation has very little energy in the shortwave region from 1,000 to 2,500 nm, while direct-beam radiation has significant energy in that region (see Fig. 12). Therefore, anything affecting the direct-beam (hence total global) irradiance, and unshaded pyranometer signal, such as variations in atmospheric water vapor, does *not* affect the *shaded* pyranometer signal. That is, for *different* atmospheric water vapor concentrations and differing direct normal and global total irradiances, the *same* "shaded" signal from the pyranometer is possible. The light areas between the global-irradiance plots show the difference between the low and high water vapor conditions. The concomitant changes in the diffuse spectral distribution are minimal. For essentially the same diffuse radiation, varying water vapor content results in changes of up to 0.5% in shaded/unshade responsivities for both all-black and black-and-white detector pyranometers with respect to the global reference spectrum.

Solar Radiation for Solar Energy Utilization. Figure 8
Traceability diagram and buildup of uncertainty through calibration transfers for radiometers

Geometric, Environmental, and Equipment Uncertainty Additional well-known contributors to radiometer calibration and measurement uncertainty include accuracy of the calculation of the zenith angle, non-Lambertian cosine response of the detector surface (see Fig. 13), temperature coefficients, linearity, thermal electromotive forces (sun shining on connectors), and electromagnetic interference (EMI) [38]. Finally, the specifications and performance of the data-logging equipment (resolution, precision, and accuracy) deployed in the field must be considered. Table 2 lists these uncertainties.

Pyranometer Responsivity Functions A pyranometer responsivity function derived from calibration data should be used to retrieve accurate irradiance from a pyranometer. The uncertainty in each pyranometer calibration responsivity *point* in Fig. 11 is summarized in Table 2. The expanded uncertainty for each point in the curves of Fig. 11 is about 1.8%, with coverage

factor $k=2$. This is the *smallest* uncertainty that can be expected of a pyranometer under conditions identical to the calibration conditions, including the "thermal offset" conditions, at a specific zenith angle. It is possible to *estimate* the thermal offset during calibration, using longwave radiometers (pyrgeometers, with their own inherent uncertainties) and compensate for this effect during calibration [44–47]. Responsivity at a given zenith angle at the time of measurement, Rs(m), can be obtained from a fit to the response curve from calibration data versus zenith angle. Figure 13 shows approximately ±1% repeatability for the responsivity functions for a single all-black detector pyranometer over seven component summation

Solar Radiation for Solar Energy Utilization. Figure 12

calibrations in a 2-year period. For radiometers deployed to the field, further sources of uncertainty arise, such as differing accuracy or resolution data recorders, cleanliness, and climatological conditions (i.e., varying net-infrared exchange conditions) – all of which may exist in addition to the calibration uncertainty computed in Table 2. This will lead to field measurements with uncertainty greater than the 1.8% calibration uncertainty [46].

Pyrheliometer Uncertainties As described in the section on "Pyrheliometer Calibrations", pyrheliometer signals are compared directly with the reference (cavity) pyrheliometer signals. There are no concerns with geometric response, computation of the zenith angle, or apparent thermal offsets (nighttime data $\sim \pm 1.0$ W/m^2). Many of the contributions to total uncertainty listed in Table 3 disappear. However, there are new contributions to uncertainty: Pyrheliometers have windows for continuous outdoor operation, and the reference pyrheliometer has no window. This may lead to spectral effects similar to those seen with respect to pyranometer domes. Errors in tracking the sun may arise because the reference pyrheliometer and pyrheliometer must be pointed at the sun. The fields of view of the reference cavity radiometer and pyrheliometer may be different. This would make the calibration dependent on the circumsolar radiation field. The final tally of the pyrheliometer uncertainty components is shown in Table 3. The expanded uncertainty for each Rs is 1.6%. With deployment to the field, pyrheliometer data become subject to additional tracking and window cleanliness issues, differing data logger specifications, etc. These require additional analysis specific to the deployment for estimating a total uncertainty in the field measurement, which must be greater than the 1.6% calibration uncertainty [48].

Solar Radiation Measurements Summary

Today's broadband solar radiation measuring instruments, absolute cavity radiometers, pyranometers, and

Solar Radiation for Solar Energy Utilization. Figure 13
Repeatability of responsivity functions for a single all-black detector pyranometer over seven calibration events in a 2-year period

pyrheliometers use improved materials and manufacturing processes above and beyond their historical predecessors. Fundamental accuracy for direct-beam and total hemispherical solar radiation as low as 2–5% or better is achievable with simple calibrations. An improvement by a factor of 2 in uncertainty to about 1.5–2.5% is possible *only with extensively characterized instrument responses*, or applications requiring only a very narrowly defined set of conditions (zenith angle or solar geometry). These percentage uncertainties translate to absolute magnitudes of 15, 25, and 50 W/m^2 for clear-sky irradiances of 1,000 W/m^2. Global climate change and general circulation models (GCMs) produce results relating to global warming, temperature trends, and fluctuations that are derived from changes in the Earth's radiation budget of only 1, 2, or 5 W/m^2. Further, the global average daily solar input is only about 325 W/m^2 at the Earth's surface. The GCMs are reporting changes of only 0.3–1.5% in this average value. Only one solar radiation measurement instrument, the absolute cavity radiometer reference pyrheliometer, has accuracy approaching the 0.3% lower value. All other solar broadband measurements have an accuracy exceeding this fundamental lowest limit. Therefore, it is very difficult to verify with any great accuracy the predictions of GCM radiation budget results using current broadband solar radiation instrumentation. A great deal more work in the field of solar radiation measurements needs to be done to significantly shorten the time required to answer questions critical to the energy economy of the planet and human societies.

Modeling Solar Radiation Resources for Solar Energy Conversion

Determining the component(s) – hemispherical, direct, or diffuse – of solar radiation applicable to a conversion system is the first step in evaluating design criteria and performance. Systems with concentrating optics rely on the availability of direct-beam radiation. Low-concentration systems may be able to utilize some diffuse sky radiation through "light trapping" techniques. Flat plate collectors, fixed or variable in their mounting, can utilize all radiation components, including reflected ground radiation from behind the panels in the case of bi-facial modules. Buildings and daylighting applications require solar components

contributing to heat loads or available for skylight and window configurations. Most often, the only available measured or modeled solar radiation data are global horizontal total hemispherical radiation. In this case, "conversion" models are used to derive *estimates* of the appropriate quantities. The solar radiation scientific research community, peer-reviewed publications, and published reports are presently relied upon to evaluate, validate, and assess the quality of these conversion algorithms [49]. Table 4 lists the types of solar radiation data needs often requested for specific applications.

Given the variety of solar radiation applications, and the small number of available measurements,

Solar Radiation for Solar Energy Utilization. Table 4 Data formats requested by solar energy system designers and planners

Type of solar data	Time resolution	Application
Hemispherical, vertical surface, cardinal directions	Seasonal/daily	Glazing, building energy balance
Illuminance, vertical surfaces, cardinal directions	Seasonal/daily	Daylighting
Hemispherical tilt	Monthly/annual	Fixed flat plate
Hemispherical tracking	Monthly/annual	Tracking flat plate
Direct normal (beam)	Monthly/annual	Focusing/concentrating system
Sunshape (disk+circumsolar) variation	Varies	Concentrating tracking collector
Monthly mean daily total	Monthly/daily	Economics, design specification
Monthly mean	Monthly	Economics, design specification
Daily profiles	Hourly	System simulation, design, rating
8,760 hourly data for year, hemispherical and/or direct	Hourly	System simulation, design, rating
Hourly time series 10–30 year hourly power	Hourly	Performance and economics, system lifetime
High time resolution time series daily profiles power	Sub-hourly	System transient response

models are frequently needed to provide suitable information for solar energy conversion systems. The following sections describe the principles of modeling solar radiation to meet the requirements for such a wide variety of applications.

Solar Radiation Model Approaches

Long-term measured solar radiation data sets are rare, have variable periods of record (with usually many data gaps), and vary in their ease of access. Measurement networks or stations providing high-accuracy, "up-to-the-minute" measured data are typically oriented toward scientific research and are rare. Agricultural research station solar radiation data for total horizontal solar radiation of highly variable quality is available, usually from state agricultural agencies. However, this data can be episodic (e.g., growing season only) and requires careful evaluation and comparison with other (perhaps estimated or modeled data) sources to establish its appropriateness for use. As a result of the lack of definitive solar radiation measurements for applications listed in Table 4, many models and modeled data solar radiation sets have been developed. Muneer [50, 51], Iqbal [52], and Badescu [53] all describe a myriad of model approaches. The most common models and data sets address total global hemispherical on a horizontal surface, occasionally the direct beam, and sometimes diffuse hemispherical on a horizontal surface.

There are several approaches to modeling solar radiation data. Empirical or parametric models are based on correlations developed between input "independent variables" and solar radiation data. Regression analysis is applied to express the solar radiation parameter in terms of the independent variables. Examples of independent variables often used are sunshine hours, temperature, cloud cover, and so on. Caution is needed in this approach, as the "independent" variables are often cross-correlated (e.g., temperature can be correlated with the solar radiation and relative humidity with temperature and dew point). This multicollinearity results in inflated correlation and sometimes unstable model coefficients derived from the regressions. These models are often site-dependent and not generally applicable worldwide, unless the development data sets are very comprehensive.

Physical models are based on principles of physics, radiative transfer, and the properties of the atmosphere. These models can be complex and require

esoteric, rarely found input parameters. Examples are cloud droplet radii, aerosol size distributions, single scattering albedo, and so on. On the other hand, simple transmission and scattering functions for the atmosphere can be derived from the complex functions in the most complicated physical models. These models often first generate clear-sky direct-beam radiation and use correlations or special algorithms to generate the total hemispherical and or diffuse sky radiation. Examples include Bird and Hulstrom [54], and Gueymard [55]. Survey articles covering such models have been published by Ineichen [56], Wong and Chow [57], Muneer [58], and Gueymard [59]. The model output is usually the product of the extraterrestrial solar radiation and the transmission functions, along with any geometric considerations. An example of a model for all sky conditions is that of Kasten and Czeplak [60].

Satellite-based models transform brightness (radiance) data from images into solar radiation fluxes at the surface. A combination of physical and empirical correlations of solar radiation with variables such as surface albedo, cloud cover, and relations between radiation components are then used to produce radiation total hemispherical, diffuse sky on a horizontal surface, and direct-beam radiation components. Figure 14 illustrates how various gridded layers of information from satellite images (pixel brightness) and ancillary information about atmospheric constituents, ground albedo, etc., are combined to produce surface flux estimates.

Detailed descriptions of these models – including the concepts of cloud index formation for modifying clear sky irradiances and derivation of the total hemispherical, direct-beam, and diffuse sky components – can be found in Cano et al. [61], Diabaté et al. [62], and Perez et al. [63].

Solar Radiation for Solar Energy Utilization. Figure 14 Gridded layers of information to be combined to estimate solar fluxes from satellite imagery

Temporal Resolution The most prevalent time resolution for solar radiation data (measured or modeled) is hourly average data. Measured data are usually averaged over an hour, based on measurements at higher-resolution (e.g., 1-, 5-, or 10-min) intervals. The underlying higher time-resolution data are usually not available. The WMO World Radiation Data Center (WRC) in St. Petersburg, Russia, is the designated WMO archive for daily solar radiation data in the form of daily total radiation, typically global hemispherical radiation, summed over daylight hours. Often, only monthly averages (e.g., monthly average daily total of hourly data) are popular to evaluate the suitability of a proposed solar energy conversion system. Efforts at making both measured and modeled higher time-resolution data (e.g., intervals of less than 1 h, down to 1 min, or even less) are under way. Such high-resolution data are just beginning to be considered because of the impact of the transient response of large photovoltaic systems might have on the stability of the electric grid over long [64] and short periods [65].

Period of Record Few sets of measured data for long periods of record (i.e., more than a few years) are available to the public. Examples are the University of Oregon Solar monitoring network (since 1975 at some sites), the National Renewable Energy Laboratory Solar Radiation Research Laboratory (since 1981), the US Department of Energy (DOE) Atmospheric Radiation Measurement sites (since 1997), and the BSRN (since approximately the mid-1990s but varies by station). Some modeled data sets, such as the US National Solar Radiation Data Base (NSRDB) and the National Aeronautics and Space Administration (NASA) Surface Solar Energy data set (NASA SSE) contain modeled data over extended periods of time (20–30 years). The NSRDB host hourly data; the highest time-resolution NASA SSE data are daily totals. Stations in the WMO/WRC data archive report daily totals (usually of percent sunshine and/or global horizontal daily totals), and the period of record for individual stations varies widely from a few months to years.

Modeled Data Sets

A sample of modeled data sets available to the public, either free online or for purchase, are the NSRDB, the Swiss Meteotest METEONORM software, the European Solar Radiation Atlas and other European data sets, the NASA SSE Data Set, and the DOE EnergyPlus weather data sets.

An important popular modeled data set is the so-called "Typical Meteorological Year" (TMY) for a specific location. TMY data sets were originally designed for building heating and cooling load calculations. The TMY consists of 8,760 hourly data points for a single, synthetic year. Data for a given TMY month are "near" (but *not* "equal to") the weighted mean of meteorological parameters (e.g., temperature, wind speed, etc.) and solar radiation for all months in the period of record (generally, 30 years is preferred) that the TMY represents. The representative months may come from different years but are spliced together to give the continuous yearly time series. These data sets are used mainly to evaluate *relative performance* of different conversion system designs with respect to a "standard" data set and *may not be appropriate for optimizing performance*. The DOE EnergyPlus data sets contain TMY-derived and TMY-like data sets for many world cities, as well as access to some real-time measurement data.

The primary objective of many of the models described above is to compute total (global) hemispherical irradiance, sometimes decomposed into the direct normal irradiance and the sky diffuse irradiance. Examples include the METSTAT model of Maxwell [66] and models based on meteorological inputs, as described by Muneer [58]. The next step is to try and estimate the solar resources available on various solar energy collector configurations. This means algorithms are needed to convert either available measured or modeled data (e.g., total hemispherical on a horizontal surface) to the radiation on some other configuration – a tilted plane, tracking focusing collector, window area, tilted roof, or building façade. These conversion or transposition models are discussed in the following sections.

Estimating Hemispherical Radiation on a Tilt

Tilted surfaces may be fixed or variable in tilt angle. Examples of the former are south-facing surfaces tilted at the latitude of a location and vertical surfaces facing various azimuth directions. Examples of the latter are surfaces that track the sun or change their tilt from vertical east at sunrise, to horizontal at noon, to vertical west at sunset. The radiation falling on these surfaces is made up of components from the direct beam (if the surface is hit by the beam radiation), a portion of the sky radiation from that portion of the sky seen by the surface, and ground-reflected radiation within the field of view of the surface. Figure 15 illustrates these components.

Solar Radiation for Solar Energy Utilization. Figure 15
Schematic of solar radiation components for a tilted surface

Similar to horizontal surfaces, the incidence angle, i, of the direct beam with respect to the normal perpendicular to the surface will determine the contribution of the direct-beam component on a tilted surface (hereafter called plane of array, or POA), Bt, through the relation $\mathrm{Bt} = B\cos(i)$. The contributions of the portions of the sky and ground-reflected radiation hitting the POA are much more variable and difficult to describe without direct measurement of the total hemispherical radiation in the POA. If the total hemispherical radiation on the POA, Hs, can be measured, and the direct beam, B, can be measured independently, the total diffuse on a titled surface, Fs, can be computed using the relation $\mathrm{Fs} = \mathrm{Hs} - \mathrm{Bt} = \mathrm{Hs} - B\cos(i)$.

Note that the total diffuse on a tilted surface, Fs, is the sum of the sky radiation, Ss, and ground-reflected radiation Gs, or Fs = Ss + Gs. It is a difficult measurement problem to separate the sky and ground-reflected radiation from the total hemispherical radiation less the incident beam radiation on a POA. However, models have been developed to accomplish this, depending on the optical properties of the ground in the field of view of the tilted surface.

Many models have been derived for computing hemispherical radiation on a tilt from global horizontal hemispherical radiation. Gueymard [67] evaluated ten models. The most accurate models use at least two measured components to compute the irradiance on the tilted surface; however, a few (less accurate) estimate the irradiance on a tilted surface from a single parameter, usually global horizontal irradiance. Validation of the modeled data against experimentally measured data has shown that these models possess systematic bias errors of 2–5% and random errors of 5–10% with respect to the validation data sets. One of the most popular and accurate of the former is the Perez Anisotropic Model for Diffuse on a tilted surface [68]. This model is embedded in many flat plate photovoltaic performance models. The Perez model was developed using hourly average data and thermopile radiometer data. The Perez model has systematic and random errors on the lower end of the range of errors mentioned above. Applicability of the Perez model, or any of the transposition models, to higher time-resolution (e.g., sub-hourly) periods or data derived from non-thermopile radiometers is also an open research question.

Estimating Direct Beam (DNI) from Global Horizontal Radiation One of the few models to estimate direct beam from global horizontal radiation is the Maxwell DISC (Direct Solar Insolation Code) and the Perez variation on this approach, DIRINT. This model is based on empirical relations between clearness indices [69, 70] Kt, the ratio of ground global hemispherical radiation to extraterrestrial radiation (ETR) on a horizontal surface, ETR $\cos(Z)$, and Kn, the ratio of ground-measured direct beam to ETR direct beam. The model was derived using hourly average data and thermopile radiometer data. Applicability to higher time-resolution data and non-thermopile radiometers, which do not sense the entire solar spectrum, is an open research question. Basic systematic error in the DISC model is around ± 50 W/m^2, with random errors on the order of ± 150 W/m^2 in hourly data. The model was developed and validated using mid-latitude data in the United States, so it may not have included a wide enough range of solar elevation angles to be appropriate for worldwide application. However, Perez et al. [70] evaluated the model for northern European as well as US sites with results similar to those quoted above.

Estimating Diffuse Hemispherical Radiation from Global or DNI Under clear and partly cloudy conditions, diffuse sky radiation is often a relatively small part (<30%) of the total hemispherical radiation. Under dense overcast conditions, the global hemispherical and diffuse sky radiation should be identical. When diffuse sky measurements are not available, estimates of the diffuse may be needed in conjunction with global hemispherical data to estimate direct beam (as in the Maxwell DISC model discussed above). Diffuse sky radiation is also useful for daylighting applications. Many models based on empirical correlations between global hemispherical and diffuse sky radiation data have been developed. Liu and Jordan developed a model for estimating monthly average hourly diffuse. Examples of algorithms for estimating hourly diffuse have been developed by Orgill and Hollands [72], Erbs et al. [73], Spencer [74], Iqbal [52], and many others. These algorithms generally use correlations of global clearness index, Kt [hemispherical radiation divided by ETR $\cos(Z)$] and Kd [diffuse sky radiation/ETR $\cos(Z)$], which have relatively large (~30%) scatter about regression formulas of Kd vs Kt.

Solar Radiation for Solar Energy Utilization. Table 5 Typical model and validation measurement data uncertainty limits

Uncertainty source	Total hemispherical (%)	Direct normal (%)	Diffuse (%)
Measurement (development/validation)	6	5	6
Station meteorological data bias	2	4	2
Station meteorological data random (2 sigma)	8	15	8
Total expanded uncertainty: station meteorological model	10	16	10
Satellite data bias	0	4	1
Satellite data random	5	14	5
Total expanded uncertainty: satellite model	8	15	8

Model Estimate Uncertainties Empirical models derived from measured data correlations with "independent" parameters inherently carry measurement uncertainty embedded in the ultimate model accuracy. Models based on 2% or 5% or 10% accurate data can be no more accurate than the data used to generate the model. Typically, scatter about model regression lines increases the random component of uncertainty further. Models based on first principles of physics and radiation transfer cannot be validated or verified to accuracy any greater than that of the measurements. The typical accumulation of uncertainties, including validation data uncertainties similar to the accumulation of calibration transfer uncertainty in Fig. 8, is shown in Table 5. In this table, "measurement" uncertainty accounts for accuracy of measurement instrumentation as discussed in "Radiometer Calibration Sources of Uncertainty" section, accounting for sources of additional uncertainty in field measurements, such as environmental influences, above and beyond calibration uncertainty. "Station meteorological" and "Satellite data" systematic (bias) and random values are typical values derived from mean bias differences and root-mean-square published in available satellite model validation studies. "Total expanded" uncertainties are root-sum-square combinations of the bias and (two-standard deviation) random components of uncertainty along with the measurement component, which cannot be eliminated. The latter, measurement component, is itself treated as random to account for the wide variety of conditions in which the limits of uncertainty can be achieved. For the satellite data, additional sources of uncertainty – such as poor spatial resolution at high latitudes imaged at low incidence angles and coarse (typically 15- to 30-min) time resolution of images – can come into play.

Sample benchmarking of satellite-based data by the European Management and Exploitation of Solar Resource (MESOR) group has arrived at similar uncertainties for daily average estimates for total hemispherical radiation of about 9% and 20% for direct-beam radiation. Model versus measurement validation of many of the empirical and "station"-based models can be found in Muneer et al. [58].

Future Directions

The imperative to develop clean, quickly deployed, cost-effective, sustainable, and solar energy conversion systems will require more abundant and accurate solar radiation data and models. The measurement technology now in use is more than 40 years old and not adequate to meet many of the needs of the financial as well as technical communities. The mantra of "more, faster, better, cheaper," with the additional need of "higher accuracy" is highly applicable to the solar radiation measurement needs of today and the future. Instruments with improved characteristics and lower cost can be achieved with the advances in materials and detector technologies occurring now and over the past few years. Historical solar radiation data are becoming of less importance relative to data representing the present conditions where new systems might be deployed. It is much more difficult to rehabilitate old, less-accurate data than to produce very good measurement data in the first place.

Better solar instrumentation is needed to monitor more closely the performance and degradation of installed systems to ensure reliable and consistent

energy supplies. Financiers are more likely to fund those projects in which the projected risks have been mitigated by high-quality resource and performance data. For many years, 5% accuracy for solar resource data has been considered adequate. With potential investment in tens, hundreds, and thousands of megawatts of generating potential (and corresponding units of currency), single-percentage differences amount to large amounts of money (and risk).

Both measurements and modeling at much higher resolution in time and space are needed to meet the demands of risk reduction. Operational solar plants will rely on relative dense measurement networks, spread over square kilometers, to monitor system performance and identify potential problems, as well as help plan for the mitigation of transient events such as cloud passage. Forecasting models will be needed to address the next 15 min, 1 hour, 1 day, and 1 week of operations so that reliable, continuous operations of a stable input to the electrical grid can be provided. Operational considerations such as repair/replacement and cleaning of solar conversion system will depend on having adequate resource forecasts and performance data all derived from much-improved solar measurements or models that engender trust in the physical and fiscal operators of solar power plants, whether on a single building roof or a utility-scale implementation.

Applications of solar radiation measurement and model data include predicting heat and cooling loads – from the single building to city and statewide scales. These loads are directly related to energy demand and may result in integration of some aspect of solar radiation monitoring into the new "smart grid" applications of the future.

Lastly, the question of mankind's impact on the global climate and redirection of trends in climate change that can be addressed by human intervention depend on data of adequate accuracy to make a timely decision regarding human activities. More accurate measured data, and models validated to higher accuracy based on such data, provide a larger safety margin for making a timely effort to correct problems of any nature – but none more important than the climate future generations will live under. For these reasons, at least, improved solar radiation measurements are needed. A small investment in this area could be leveraged many times over both energy and climate environments.

Satellite-based observations of Earth are incrementally being improved in terms of time, space, and signal resolution. However, these resources depend on a few countries' ability to finance the design, construction, launch, maintenance, and eventual replacement of these sophisticated tools. The replacement time for these tools can be years, and the risks involved in a stressful launch are not always small.

Direct ground-based observations will always be considered the most definitive type of solar resource data and the basis for the validation of any model, no matter how sophisticated. Such measurement stations will be more accessible than any space-based observation and much more flexible. With denser, more capable, and rational measurement networks, nagging questions about long-term trends, microclimate effects, and statistical variation in multiple space/time coordinates can be addressed and quantified. More capable, accurate, and useful (in terms of worldwide, generally applicable) models will be a result of improved measurement density, accuracy, and temporal resolution. At this point, the need for these improvements is being realized. The action items that need to be undertaken are just beginning to be addressed.

Albedo Whiteness or reflectivity. The ratio of outgoing to incoming radiation power.

Cloud condensation nuclei The small fragment of material needed to start the growth of a cloud drop when the local relative humidity exceeds 100%.

MODIS An acronym for moderate resolution imaging spectroradiometer. This is an instrument carried by two NASA satellites Aqua and Terra. The systems measure 36 spectral bands of radiation of the entire earth surface. Results are available free and are an invaluable aid to research into climate change.

Permafrost Ground which remains frozen throughout the year. It can trap very large amounts of methane which would be released if it were to melt.

Positive feedback A change in the value of a variable which leads to a further change in the same direction. It can often produce explosive effects and oscillations.

Relative humidity The ratio of the amount of water vapor in a parcel of air to the maximum amount that it could hold if nucleating particles were present. Values can exceed 100% and even reach 300% if all nuclei are absent.

Solar constant The rate at which solar energy of all wavelengths crosses unit area at the top of the atmosphere. It is about 1,366 W/m^2 but is strictly not quite constant. There are cyclical variations with an amplitude of about 3.5% due the ellipticity of the earth's orbit around the sun, 11 year cycles and faster random variations of about 0.1%.

Twomey effect The relationship of cloud albedo to cloud depth, liquid water content and concentration of cloud condensation nuclei elucidated by Sean Twomey. His work began following observation of increased albedo of ships tracks in satellite photographs.

Definition of the Subject

Cloud albedo enhancement is one of several possible methods of solar radiation management by which the rate of increase in world temperatures could be reduced

or even reversed. It depends on a well-known phenomenon in atmospheric physics known as the Twomey effect. Twomey argued that the reflectivity of clouds is a function of the size distribution of the drops in the cloud top. In clean mid-ocean air masses, there is a shortage of the condensation nuclei necessary for initial drop formation in addition to high relative humidity. This means that the liquid water in a cloud has to be in relatively large drops. If extra nuclei could be artificially introduced, the same amount of liquid water would be shared among a larger number of smaller drops which would have a larger surface area to reflect a larger fraction of the incoming solar energy back out to space.

Introduction

At noon in the tropics, the top of the Earths' atmosphere receives about 1,350 W/m^2 from the sun. This is known as the solar constant but varies slightly with solar activity and orbital changes. Because of the high source temperature, most of the solar energy is spread over the short wavelengths – those to which our eyes have evolved. Some is reflected back to space, and some is absorbed by gases and particles in the atmosphere, thereby increasing their temperature. The amount reaching cloud level over 24h is about 440 W/m^{2}at the equator and about 340 W/m^2 globally. Some radiation is absorbed by clouds. Some passes through to reach the ground. Radiation from bodies at lower temperatures is at much longer wavelengths where atmospheric gases have different absorption properties.

Changes in the concentrations of atmospheric gases will affect the amount of heat retained, and the temperature then has to rise to restore the energy balance by increasing outward radiation. While much attention is given to carbon dioxide, many other gases are involved, some with stronger absorbing properties, particularly water vapor and methane. The maximum atmospheric water vapor concentration increases with temperature giving a positive feedback, but it can be rapidly returned to the sea as precipitation and condensation. A more abrupt and less reversible positive feedback could be triggered by the release of methane from melting permafrost.

It is widely thought that the change of atmospheric carbon dioxide and other greenhouse gases since pre-industrial times together with the resulting water vapor amplification has increased the amount of heat retained by the earth at a rate of about 1.6 W/m^2. This is only 0.0047 or one part in 212 of the 340 W/m^2 mean 24 h input. It is therefore possible that a very small increase in the reflectivity of the earth could reduce, cancel, or even reverse the anthropogenic increase and so provide time for the development of low-carbon energy sources and carbon sequestration.

Clouds cover a substantial fraction of the earth's surface and are good reflectors of solar energy. However, cloud drops cannot form without an initial small "seed" known as a condensation nucleus. In 1990, John Latham [1] proposed that the reflectivity of marine stratocumulus clouds could be increased by spraying submicron drops of sea water into the marine boundary layer. The drops would evaporate to leave salty residues. Air flows in the marine boundary layer are quite turbulent, and the residues would soon be well mixed through it. Salty particles are hydrophilic and so are ideal condensation nuclei. The most effective size range for nucleation is between 0.5 and 1 μm. Those nuclei which reach cloud level provide the seeds for new drops and so trigger the Twomey effect. Twomey [2] argued that the reflectivity of a cloud depends on its depth Z in meters, the liquid water content L in milliliters of water per cubic meter of air, and the drop concentration expressed in the number per cubic centimeter.

It may be convenient to rewrite the equations in Twomey's original paper with an intermediate term $K(Z, L, n) = 0.15\, Z\, L^{2/3} n^{1/3}$. Cloud albedo A is then

$$A(Z, L, n) = \frac{K(Z, L, n)}{K(Z, L, n) + 0.827}$$

Figure 1, adapted from Schwarz and Slingo [3], shows a plot of the relationship. For the typical range of conditions, a doubling of the number of nuclei will increase reflectivity by 0.056 from an initial value of 0.3–0.7. The vertical bars mark present condensation nuclei concentrations for clean mid-Pacific air and dirtier Atlantic air suggested by Bennartz [4] based on analysis of satellite observations.

It is the fractional increase in the number of nuclei in the effective diameter range that matters, not the amount of water sprayed. This means that the technique is far more effective in clean air and has

Solar Radiation Management, Cloud Albedo Enhancement. Figure 1
Twomey's results for cloud albedo as a function of cloud depth, a typical liquid water content of 0.3 g/m^3 of air and drop concentration (Adapted from Schwarz and Slingo [3] with Bennartz [4] data for drop concentration)

Solar Radiation Management, Cloud Albedo Enhancement. Figure 2
Cloud droplet concentration for warm clouds as estimated by the MODIS instruments (Courtesy of NASA and Robert Wood of the University of Washington)

diminishing returns as treatment progresses. If atmospheric observations are taken from short-range aircraft, there will be a bias towards higher numbers. Figure 2 shows worldwide drop concentration supplied by Wood [5] from the MODIS instrument on Aqua and Terra satellites [6]. Large areas of mid oceans have concentrations below 50 cm^{-3}. In some air masses, which have been over Antarctica for long periods or washed by recent rain, the concentration can be as low as 10 cm^{-3}. In contrast, values over land can be 1,000–5,000 cm^{-3}.

Latham found that, with the correct drop size, the amounts of spray needed to give a useful reduction of incoming power are surprisingly small. Figure 3 shows cooling for 340 W/m^2, a fairly typical selection of cloud depth liquid water content, the nuclei concentrations suggested by Bennartz and their mean. There is some uncertainty about lifetime of the condensation nuclei. This graph uses a half-life of 59 h from Smith et al. [7] and is in good agreement with Hoppel et al. [8] which shows half-life as a function of drop diameter. If the assumptions on the right of the figure are reasonable,

assumptions and sources

boundary layer depth	1000 m
cloud depth	300 m
Schwartz and Slingo (1996)	
liquid water	0.3 ml m^{-3}
Schwartz and Slingo (1996)	
drop life	59 h
Smith et al. (1991)	
low, not high, cloud fraction 0.18	
Charlson et al. (1987)	
initial albedo	0.495
24 h power in	340 Wm^{-2}

Solar Radiation Management, Cloud Albedo Enhancement. Figure 3
Global cooling as a function of spray rate for the assumptions in the table to the right. The circle shows 1.6 W/m^2, often taken as a figure for anthropogenic change since pre-industrial times. The question mark might be the result of a doubling of carbon dioxide

then the thermal damage since pre-industrial times could be offset by spraying about 10 m^3/s worldwide.

Several independent climate models [9, 10] support the effectiveness of Latham's proposal, and in some conditions, in clouds with no internal drizzle, the models predict an albedo change exceeding 0.4. In very rare circumstances with exceptionally clean air, it may be possible to produce clouds from a clear sky. However, the intention is to make existing clouds whiter.

Energy Requirements

The minimum energy requirement to produce a drop is the product of its surface area and its surface tension. For sea water, the surface tension is 0.078 N/m, a little higher than for fresh water, so making a 0.8 μm diameter drop needs at least 1.57×10^{-13} J. When a condensation nucleus reaches the cloud level, it will split an existing drop into two smaller ones with the same volume of liquid but with a reflecting area increased by the cube root of two, about 1.26. Figure 4 shows the range of drop sizes (in radius as used by scientists, not in diameter used by engineers) with much larger ones over mid ocean.

The solar energy that will be reflected by the two new drops will depend on the input power density, the time before the two drops coalesce and the effective reflection coefficient. The reflection coefficient of drops is an extremely complicated function, Mie [11] Laven [12], of wavelength, polarization, and angle of incidence but is of the order of 10%. Few people can believe the magnitude of the ratio of energies of reflected solar radiation to nucleus creation until they have done the calculations for themselves. Figure 5 demonstrates the effect of drop sizes on reflectivity using glass balls.

Treatment Sites

Good sites for spraying need incoming sunshine, low marine stratocumulus clouds, and clean air. The clean air requirement points to regions away from land masses and shipping routes. The sunshine requirement suggests the ability to migrate with the seasons so as to make use of the long hours of summer sunshine at high latitudes. The cloud requirement is less critical than the other variables. Cloud coverage may be inversely related to longer drop life. Spray produced under clear skies evaporates to leave a crystal of dry salt which would be much smaller than the typical 25 μm diameter liquid drop in a cloud but which would have an albedo well above a liquid drop and a lifetime which could be much longer. Furthermore, it is better to have a low dose over wide a area, and spray under clear skies would be more widely dispersed. It might be attractive to spray in air which we expect will later move to a cloudy region.

Solar Radiation Management, Cloud Albedo Enhancement. Figure 4
Cloud droplet *radius* derived by Breon Tanre and Generoso (Courtesy of Science. From http://www.sciencemag.org/content/295/5556/834.full.pdf)

Solar Radiation Management, Cloud Albedo Enhancement. Figure 5
The jar on the *left* contains 4 mm glass balls. The *grey scale* behind the jars has 10 bars going from roughly zero to nearly 100% whiteness depending on your printer and paper quality. This shows that the albedo of the 4 mm balls is about 0.6. The jar on the *right* contains 40 μm glass balls, 100 times smaller, and has an albedo of about 0.95

Mobility, energy, and long duty periods can be provided by unmanned sailing vessels. The chief engineering problem is the production of the correct diameter spray from a mechanism with a long service life, low energy requirements, and no need of supplies from land. A narrow range of diameters may reduce the probability of drop collision leading to coalescence which would shorten drop life and it may turn out to be useful to adjust diameter with remote commands. A number of techniques are being studied by Neukermans (2010, 2011, personal communication), Salter [13].

Environmental Impacts

Evaporation of water from the oceans is about 14 million tonnes a second of which about 12.8 million tonnes per second is precipitated back to the sea. There is no need to fear anything from the direct water output from spray vessels.

Breaking waves produce a wide range of drop sizes all over the oceans but especially at beaches. It is not easy to get a number for the salt transfer but Blanchard [13] explains the ways that an attempt could be made. Grini et al. [14] survey more recent estimates. These range from 1000 to 10,000 million tonnes a year or from 30 to 300 tonnes a second. Ten tonnes of sea water, a second needed to cancel 1.6 W/m^2, would transfer 350 kg of salt per second. What makes the salt from spray vessels so much more effective is the controlled size of the salt residues. Most of them would be returned to the sea and so would be very small compared with spray from beaches, much of which goes inland.

However, Victorian doctors knew very well that sea air was good for lung infections. A Polish doctor F Boshkowsky noticed that his patients who worked in the salt mines had no lung illness and enjoyed long lives despite hardworking conditions. In Eastern Europe, salt mine exposure is used for treating asthma, and in the West, there is a brisk trade in salt pipes. There is no need to worry about the effect of salt from spray vessels on human health.

The immediate effect of albedo control is a reduction of the sea surface temperature below the treated cloud. The reduction will be small compared with the normal changes from cloud to clear sky and even less compared with the change from day to night. But sea surface temperatures are a very strong driver for many other meteorological parameters. The laws of thermodynamics predict that although the effect will eventually diffuse worldwide, there can also be local deviations, and operators will have to build up a clear understanding of all the outcomes.

The greatest anxiety about side effects concerns changes to precipitation. Changes in either direction could be bad. During 2010 and 2011, there was severe drought in Russia and the most violent flooding in Pakistan, Queensland, Brazil, and Sri Lanka before anyone had attempted any form of intentional geoengineering. It may be that we have to choose the least bad outcome. But if we understand meteorology properly, we may be able to improve things in different places by drying out wet regions and getting more rain to dry ones. At least eight mechanisms are involved, and some, especially precipitation, are not well represented in present climate models. As so often in meteorology, factors can work in opposite directions, and we may be ignorant even of the polarity, let alone the magnitude, of the final outcome.

The mechanisms so far identified are:

1. The production of rain needs some large drops to fall through deep clouds fast enough to coalesce with other drops in their path so that they grow large enough to fall fast enough to reach the ground without evaporating in the dry air below a cloud. It is known from Albrecht [15] and Konwar et al. [16] that rain is less likely if there are too many small drops due to smoke and fine dust. This happens over land and could happen as a result of cloud albedo control but the depth of marine stratocumulus is mostly too thin to form rain and the effect might be to extend cloud lifetime.
2. However, if more small cloud drops means that there is less rainfall *over the sea*, it follows that there will be more water left in the air mass when it reaches land. The air mass will travel further inland before the original drop numbers are restored by coalescence. Rain inland is more valuable than rain at the coast.
3. Any reduction in sea temperature will tend to reduce evaporation and increase condensation from air back to the sea surface and this will reduce the water content of the atmosphere. The increase in evaporation rate increases sharply at sea surface temperatures around 28°C [17] and may have contributed to recent floods.
4. But cooling the sea means a larger difference between the temperatures of sea and land, more monsoon effect, with stronger winds bringing more water to land.
5. Wind is caused by differences in pressure which are a result of local temperature gradients. Wind causes turbulence in the marine boundary layer. The relative humidity is very high in the stagnant layer of air at distances of millimeters above the sea surface but falls to around 65% a few meters above. Turbulence has a much greater influence on evaporation rate than water temperature except at temperatures above about 27.5°C.
6. Wind makes waves steeper. Spilling breakers mix the thin top layer of water that has been chilled by evaporation and warm it with heat from below. Plunging breakers drive bubbles below the surface and throw spray above it to transfer more water vapor in the air. Evaporation rises steeply if wind speeds exceed 13 m/s.
7. If cloud albedo control at sea reduces temperatures on land, it will also reduce the evaporation rate so more of the precipitation will be retained as ground water.
8. Finally, we know that the regions with the most severe drought problems are dry because air which has been dried by being high in the atmosphere is subsiding and moving out to sea. This means what we do at sea cannot immediately affect the very driest land nearby.

A computer experiment by Jones, Hayward and Boucher [18] illustrates the possibilities. Their world climate model was set to allow the concentration of condensation nuclei to be increased in three small regions together representing 3.3% of the world area. Spray off California nearly doubled rainfall in the drought-stricken region of central Australia and caused a smaller increase in the Southern part of the Amazon basin. Spray off Peru increased rain in Brazil but reduced it in Argentina. But spray off Namibia produced a reduction of about 320 mm a year over most of the Amazon basin which could be partly offset by spray from the Pacific sites.

The spray was applied through the year rather than in any way related to the monsoon phase or wind direction and was confined to the small areas, which would probably not be realistic. But the important result of this work is that we can get changes in precipitation in either direction at distances far from the spray source. It would be no great surprise if the effects were strongly affected by the spray season relative to the monsoon cycle but this has not yet been established.

Other workers [10] have used treatment over much wider areas and have not observed similar effects. In particular, Bala [19] has found the net effect for the Indian subcontinent of widespread long-term cloud albedo control was slightly lower precipitation but a slightly greater run off from the Indian subcontinent because of slower evaporation of ground water in lower temperatures. Another result from [10] is that cloud albedo control carried out well away from the Arctic can reduce the rate of Arctic ice loss and so might prevent an irreversible tipping point. However, the better the climate modeler, the more caveats will accompany the predictions. Present models are not good at predicting precipitation.

It may be possible to use climate models to predict an everywhere-to-everywhere transfer function using pseudo random sequences of increases and reductions of the concentration numbers of condensation nuclei with different sequences in many regions. The sequences would be correlated with the computer model results of all the many meteorological parameters of interest. If small random changes are made to a signal consisting of 20 years of daily observations of temperature records, the scatter of the correlation is about 1% of the standard deviation of the variation of the original record, so very small signals can be detected. More importantly, the processes do not interfere with each other, so all can be done at the same time. By doing the correlations with variable time delays, we can gain information about the frequency response of the climate system.

Engineers know that an accurate control system needs a good way to measure the deviation from the desired state. The resulting error signal should then drive some form of correcting mechanism. Small errors need a high loop gain but require a high-frequency response with a low phase-shift if oscillations are to be avoided. Satellites, perhaps with their temperature-sensing analysis algorithms improved by true data collected from spray vessels, will be able to give fast and accurate measurements of worldwide sea temperatures. Particular attractions of cloud albedo control are that the introduction can be progressive and that the response is both fast and, initially at least, locally precise.

If we understand the flow patterns of winds and currents, we can aim immediate effects at specific regions to preserve Arctic sea ice and coral reefs or protect flood sensitive areas. Even if our understanding is not perfect, we can still apply neural network technology to guide deployment. Few people can explain how to ride a bicycle but many people can ride one. Some atmospheric physicists have said, perhaps not entirely seriously, that while saving humanity's existence on the planet might be regarded as a useful spin-off, the real value of cloud albedo control would be the gain in understanding of atmospheric aerosols.

It is reasonable to suppose that attempts to keep sea surface temperature at previous levels would be less damaging than unbridled increases which seem to be occurring now. Cloud albedo control is like adding steering, brakes and a reverse gear to an unfamiliar vehicle in which the foot of a criminal lunatic is pressing hard on the accelerator. One's first training in the use of a new machine tool should be finding the emergency stop button. It is comforting to know that if we command all vessels to stop spraying, the status quo ante will be restored in a few days. This offsets the frequent criticism of geoengineering by people hostile to it – that once you start using it you have to keep on doing it. This of course could also be an objection raised against electricity generation, sewage treatment, computing, money, and kidney dialysis machines.

If you cut the strings of a parachute, you will quickly revert to your previous, rather high terminal velocity. It is a good idea not to cut the strings until you are on the ground being dragged along by a cross wind. In fact, we only have to keep using cloud albedo control until low carbon sources have been developed and excess atmospheric carbon dioxide or methane have sequestrated down to acceptable levels. The fact that the models say that the system quickly reverts gives comfort that we have done nothing irreversible.

Future Directions

Most people working in geoengineering do so with reluctance in the fear that action may be needed before low-carbon energy technologies can be deployed or atmospheric carbon dioxide removed on a sufficient scale. Even if politically impossible, reductions in emissions could take place today; our past emissions have still to take full effect. It is also possible that carbon dioxide may not be the only source of climate change with methane from permafrost increasing fast and possibly able to take the dominant role.

However, humanity is very ingenious at inventing reasons not to take unpleasant actions and ignoring reality. There are many organizations which have to protect their investments and which have perfected the skills to lobby politicians, some of whom were the same people who played a leading part in delaying the development of renewable energy. Despite achieving no reduction in atmospheric carbon dioxide, as shown by the continued acceleration of the Keeling curve, the carbon trading market has been very profitable, and people taking the profits have no wish to have competition from a parallel thermal trading market.

The near future will see activity on computer modeling of all the possible geoengineering techniques with about half the funding aimed at discrediting the ideas. Politicians try to follow public opinion rather than lead it, and until there has been much more suffering from climate extremes, there will be no political advantage in supporting the development of practical working hardware.

However, if spray hardware can be built, there are problems about producing experimental proof of successful operation because the change of cloud brightness needed is well below the contrast detection threshold of the human eye. A possible solution involves taking a large number of satellite photographs of cloud fields, shifting them to align the spray source, rotating them to align the local wind directions, and taking a pixel by pixel average of the full set. The cloud variations will be suppressed to converge towards a middle grey while the wakes downwind of the spray source emerge from the mist. Figure 6 (left) shows a single cloud image with

Solar Radiation Management, Cloud Albedo Enhancement. Figure 6
Contrast enhancement by image superposition to demonstrate the effectiveness of small spray sources (Courtesy of NASA and Robert Wood and the VOCALS experiment)

four, mathematically generated 30-kg/s spray sources at four dispersion angles and contrast set by the Twomey equation. It would take a great deal of confidence to use the very faint vertical streak at the top left as proof. Figure 6 (right) shows the same wake patterns in 100 real superimposed images supplied from the VOCALS experiment off South America. The experiment should be done in a long cruise covering many sea areas and several months because the places where the system does not work will be just as interesting as those where it does.

Conclusions

By 2010, four independent climate models confirmed that the Twomey effect could be exploited to control world temperatures by the deliberate increase of cloud condensation nuclei produced from submicron sea spray.

One model shows that spray from small regions can affect precipitation in either direction at other, very distant regions, but this is not confirmed by studies of wider treatment areas.

With proper understanding of the results of pseudorandom increase and decrease of the concentration of cloud condensation nuclei in climate models, we may learn how to control fleets of spray vessels to obtain beneficial reduction of droughts, the prevention of floods, and increases in ice cover by the correct choices of place and season for spray operations.

The chief engineering problem for the cloud albedo system is the development of mobile, energy efficient spray sources of submicron monodisperse spray which can operate for long periods in any chosen set of mid-oceanic sites.

The effectiveness of cloud albedo control can be demonstrated with a small spray source by superimposing and aligning around 100 satellite images.

Air mass In meteorology, the air mass characterizes the transport of a large system away from where it originates (e.g., continental air mass, tropical air mass). In radiative transfer, the air mass (or, more accurately, "optical air mass") is the idealized dimensionless optical pathlength of the solar photons from the limit of the atmosphere to a specific point at the surface, relative to the pathlength corresponding to the vertical of that same point. An air mass of 1 corresponds to an overhead sun, and an air mass of about 38 to a rising or setting sun. By extension, "air mass zero" refers to conditions just outside the limit of the atmosphere. See also "Optical mass."

Albedo Overall dimensionless reflectance property of a surface, varying from 0 (perfectly black, nonreflecting surface) to 1 (perfectly white, totally reflecting surface).

Geographic information system (GIS) A computerized system that is used to analyze various layers of data that are linked to geographical locations, by merging cartography and database technology.

Global positioning system (GPS) A global navigation satellite system providing accurate location and time information at any location with an unobstructed line of sight to at least four dedicated satellites. Special GPS antennae can be used to derive information on the water vapor content of the atmosphere by measuring the propagation delay of the GPS signal.

Irradiance Radiant power of electromagnetic radiation per unit area of a surface on which it is incident. It is equivalent to the radiance of the electromagnetic source integrated over all angles. Spectral irradiance is usually measured in W m^{-2} nm^{-1}.

Langley plot Method of extrapolation of ground-based spectral measurements (with sunphotometers, in particular) to obtain the corresponding extraterrestrial value at the same wavelength. This was developed by Samuel P. Langley, based on the Bouguer–Lambert–Beer law, and is now commonly used to derive the absolute calibration of an instrument. To be valid, the atmospheric transmission must remain constant during the experiment, which is carried out throughout a very clear day or half-day.

Longwave Relates to wavelengths longer than about 4 μm, corresponding to the infrared (or thermal) part of the spectrum, which can be of solar or terrestrial origin.

Luminous efficacy Characteristic illuminance (total luminous flux incident on a surface, per unit area) created by the sun (or an artificial lamp), relative to the power radiated by the sun (or the electric power used by the lamp). Its unit is the lumen per watt.

Mie scattering Refers to the theory developed by Gustav Mie to evaluate the electromagnetic extinction caused by particles whose size is larger than molecules, or even wavelength.

Monte Carlo code Radiative transfer computer program using the Monte Carlo method, which is a statistical-numerical method of solution of complex physical problems that relies on repeated random sampling. A large number of photons are virtually sent through the atmosphere and their disposition is recorded. This method can solve many complex problems, but is computationally intensive.

Optical depth A measure of transparency of an atmospheric layer, characterizing the fraction of radiation that is altered (scattered or absorbed) along its path through that layer.

Optical mass Idealized dimensionless optical pathlength of the solar photons from the limit of the atmosphere to a specific point at the surface, relative to the pathlength corresponding to the vertical of that same point. An optical mass of 1 corresponds to an overhead sun. An optical mass can be defined for each possible radiatively active constituent, and depends on the vertical profiles of its concentration and refractive index, combined with that of pressure and temperature. The optical mass corresponding to the scattering by air molecules (Rayleigh scattering) is the optical air mass, or simply air mass.

Photovoltaics Related to the property of photosensitive semiconductor materials (like silicon) to generate a photonic current (and thus electricity) when irradiated by a light source, such as solar radiation.

Precipitable water Depth of water inside a fictitious vertical atmospheric column, after all the water vapor originally contained in that column has condensed.

Radiance Radiometric quantity describing the amount of radiation that is emitted from a particular area (e.g., of the sky), within a given solid angle. Spectral radiance is usually measured in $W\,m^{-2}\,nm^{-1}\,sr^{-1}$.

Radiative transfer Describes the energy transfer of electromagnetic radiation through absorbing, scattering, and emitting media.

Radiometry Scientific field that studies the measurement of electromagnetic radiation with instruments called radiometers.

Rayleigh scattering Extinction process for the elastic scattering of electromagnetic radiation by small particles, such as air molecules. The cloudless sky is normally blue as a result of Rayleigh scattering.

Shadowband Small arm used to block the sun in front of a radiometer. It can be a fixed band to measure diffuse radiation only, or a motorized rotating band to measure diffuse and global radiation alternatively.

Shortwave Relates to wavelengths shorter than about 4 μm, corresponding to the ultraviolet, visible, and near-infrared parts of the solar spectrum.

Solar spectral irradiance (SSI) Radiative power received from the sun at 1 AU at normal incidence on a surface of unit area (1 m^2) at a specific wavelength.

Spectroradiometry A part of radiometry dedicated to the measurement of radiation quantities in narrow spectral bands, using instruments called spectroradiometers or spectrometers.

Stratosphere Upper region of the terrestrial atmosphere extending from about 18 to 50 km.

Sunphotometry A part of radiometry dedicated to the measurement of narrow spectral bands of the solar spectrum with an instrument pointing at the sun called sunphotometer.

Total solar irradiance (TSI) Radiative power received from the sun at 1 AU at normal incidence on a surface of unit area (1 m^2).

Troposphere Lowest portion of the Earth's atmosphere, below about 18 km altitude, in which most of atmospheric extinction occurs.

Definition of the Subject

Solar radiation is significantly altered along its path throughout the atmosphere. This has important implications in many natural and technological processes, including meteorology, biology, ecology, and energy production. This entry examines the characteristics of the solar electromagnetic spectrum as it can be observed from just outside the Earth's atmosphere, how atmospheric extinction processes affect the shortwave portion of this spectrum, how all these processes can be modeled, and how the resulting spectrum can be determined experimentally. Furthermore, discussions are provided about the availability of various modeling tools to evaluate the spectral irradiance at the Earth's surface, and about sources of measured or modeled data regarding the solar spectrum.

Introduction

Life on Earth is totally dependent on the quantity and quality of the electromagnetic radiation it receives from the sun. All physicochemical processes in the atmosphere, at the Earth's surface or in the oceans, are also affected by the quantity of energy received from the sun. However, the quality of this source of energy (i.e., its spectral distribution) is also important, since most natural reactions are sensitive to certain spectral bands. The increasing use of solar radiation as a sustainable source of energy also results in the accelerated development of efficient spectrally selective materials

(e.g., for photovoltaic applications), whose optical properties must be designed or determined as a function of the incident solar spectrum.

As in many other science fields, knowledge of the properties of the solar spectrum has progressed through both measurement and theory. The difficulties here are that the spectral distribution of the solar spectrum changes over time for many different reasons, and that the spectral intensity varies by orders of magnitude over the whole possible spectral range. Contrarily to most existing radiometers used to measure spectral radiation, the human eye is well adapted to rapid changes in both intensity and visual quality of light when, for instance, a thick cloud suddenly masks the sun. Even above the atmosphere, the solar spectrum changes over time due to solar activity. Still, the major source of variability at the Earth's surface is caused by changes in atmospheric extinction processes, since many of its constituents (such as gases, particles, and clouds) vary over both space and time. Modeling the solar spectrum is needed to predict its spatial and temporal variations, and this implies the appropriate development of two different things: radiative transfer models, which must correctly simulate the main extinction processes of radiation in the atmosphere when its constitution is known, and precise supporting input data about the spatial and temporal distributions of these constituents. The current developments in these fields are discussed here.

Solar Radiation Outside of the Earth's Atmosphere

The sun is now known as a variable star. As early as 1881, Samuel P. Langley of the Smithsonian Institution conducted initial attempts to measure the solar constant from a high-altitude site (Mt. Whitney). He then initiated what became the longest program of ground observations of the sun's output, the Smithsonian "solar constant program." His assistant, Charles G. Abbot, started this new series of measurements in 1902 and continued for 6 decades. He later summarized the premises and goals of this program in a 1966 review paper [1]: "Langley suspected that this (the radiation of the sun) might be variable, and that its variation might be a cause of weather changes. If the suspected solar variations proved periodic, they might lead to long-range weather forecasts of great value for agriculture and water supply."

The large amount of data collected by Abbot and collaborators indeed revealed short-term and long-term variations in what was still called the solar constant. Because of this variability, the more proper term used now is Total Solar Irradiance (TSI). Still, the concept of solar constant is still used to refer to the long-term average value of TSI. Although the goal of the Smithsonian scientists was to detect any variations in the solar constant (which is the integrated sun's irradiance over its whole spectrum), their basic measurements were done spectrally. Substantial experimental and logistical difficulties made such measurements not accurate enough to detect TSI variations to the correct magnitude [2]. Furthermore, evaluating the transmission of the atmosphere in strong absorption bands (such as those of ozone and water vapor) introduced large uncertainties. Nowadays, instruments are much more sophisticated, precise and stable, but the difficulty just mentioned still remains when trying to evaluate the solar spectrum from terrestrial measurements. In the modern era, this "extrapolation" method has provided important milestones in the knowledge of the Solar Spectral Irradiance (SSI), also called Extraterrestrial Spectrum (ETS) [3–7], but this method's limits have probably been reached.

The current research on SSI is dominated by two approaches: direct measurement from spaceborne instruments, and physical or semiempirical models of the sun's radiative output. The existing models (e.g., [8–12]) may be necessary for long-term space-system specifications and operations [13], but are much too sophisticated for everyday use in most earth sciences or engineering/technology applications. For such instances, the use of reference spectra mostly based on spaceborne data (e.g., [14–18]) is well adapted. Since detectors used in spectrometers have only a limited spectral range, data from various instruments must usually be combined to obtain a reference solar spectrum with a sufficiently large spectral range. Various methodologies have been proposed to derive reference spectra, and a standard [19] now exists to specify the representations of solar irradiance. This standard is actually applicable not only to reference spectra, but also to measurements and physical or empirical solar models.

Space missions dedicated to spectral irradiance measurements have revolved around different spectral domains of observation, depending on scientific need. The extreme ultraviolet (EUV) was first to be scrutinized, with the goal of studying the properties of the Earth's upper ionosphere. Later, the discovery of the ozone hole led to the need of monitoring the UV spectrum as accurately as possible. In recent years, the importance of the climate change issue and the specific needs of atmospheric or climate models led to measuring a much larger part of the solar spectrum, up to the infrared (IR).

In the 1990s, the SUSIM [20] and SOLSTICE [21] spectrometers placed onboard the Upper Atmosphere Research Satellite (UARS), started to measure the UV spectrum from the Lyman-α emission line (121.6 nm) to 400 nm, and covered a large part of solar cycle 22 (1986–1996). Based on these measurements, the short-term UV variability of SSI could be evaluated [22]. Independent measurements were also obtained from three instruments that flew during the ATLAS 1, 2, and 3 space shuttle missions [23–25]. These missions lasted about 10 days each, and allowed retrieval of the instruments for postflight laboratory optical characterization. Furthermore, a comparison of the simultaneous solar irradiance measurements obtained by the ATLAS and UARS instruments showed that their absolute irradiance uncertainty was of the order of 5% [23, 25].

SOLSPEC was the first spectrometer designed to measure the visible and infrared domains (200–2400 nm) from space [24]. From the acquired dataset, two composite spectra were generated for two different levels of solar activity corresponding to the ATLAS 1 and 3 missions [17].

The most recent spectral measurement missions include: (1) the Solar EUV Experiment (0.1–195 nm) on board TIMED; (2) the XPS (0.1–40 nm), SOLSTICE (115–310 nm), and SIM (200–2400 nm) instruments onboard SORCE; (3) the NOAA-SBUV (170–400 nm); and (4) two instruments onboard ESA's Columbus laboratory on the International Space Station (ISS): SolACES (16–220 nm) and a redesigned version of SOLSTICE with an expanded spectral range (165–3080 nm). The latter two instruments are accompanied by SOVIM, which monitors the spectral irradiance at three discrete wavelengths (402, 500, and 862 nm), and also measures TSI with a broadband radiometer. The combined ISS experimental setup (SolACES, SOLSTICE, and SOVIM) is shown in Fig. 1.

A comparison between the Gueymard's moderate-resolution composite spectrum [15] (available from http://www.solarconsultingservices.com/Gueymard_ET_spectrum_2004.txt or http://rredc.nrel.gov/solar/spectra/am0/special.html#newgueymard) and the Planck distribution for blackbody temperatures of 5,500, 5,776, and 6,000 K is shown in Fig.2. For 5,776 K, the integrated blackbody irradiance equals the current solar constant value of 1,366 W m^{-2} [26]. It is clear that the sun does not behave like a blackbody below about 650 nm. It is noticeably "hotter" than its average blackbody temperature around its peak, and colder in the UV, with a sharp transition around 400 nm. Below that wavelength, a lot of structure also appears, which is caused by various emission and absorption lines.

Solar Radiation Spectrum. Figure 1
Artist impression of the SolACES, SOLSPEC, and SOVIM instruments mounted on a single sun-pointing device outside of ESA's Columbus laboratory of the ISS (*top*); the same apparatus during preflight electromagnetic compatibility laboratory tests. (Photos ESA)

Solar Radiation Spectrum. Figure 2
Solar spectral irradiance from 300 to 1,300 nm compared to blackbody distributions (from Planck's theory) at various temperatures

During periods of high solar activity, the UV part of the spectrum is enhanced, whereas the visible and IR parts remain relatively stable. Since the UV is significantly absorbed by the Earth's atmosphere, solar activity only results in minute changes in the absolute irradiance at the Earth's surface. For most terrestrial applications, a unique SSI distribution can thus be used, without considering the day-to-day changes in solar activity. In contrast, seasonal changes in the magnitude of the spectrum do occur because of the obliquity of the Earth's orbit around the sun. Like with TSI, all reference spectra are evaluated at the average sun-earth distance ($\approx$1 AU). Therefore, they must be corrected by up to $\pm$3.4%, depending on the day of the year. This correction is systematic, affects all wavelengths evenly, and can be calculated with a simple, yet accurate formula [26].

Solar Radiation and the Earth's Atmosphere

The composition of this planet's atmosphere is dominated (at 98% in volume) by nitrogen and oxygen. Some gases, such as ozone, carbon dioxide, methane, or water vapor, can absorb the energy from sun rays in various parts of the spectrum, and therefore have a strong radiative impact on solar radiation and climate in general, even though their concentration is very low in comparison with the two main gases just cited. In a broader way, all gases contribute to the atmospheric extinction of solar radiation through molecular scattering – the process that creates the blue color of the atmosphere. This was demonstrated by Lord Rayleigh at the end of the nineteenth century. His theory applies to the interaction of electromagnetic radiation with microscopic particles (in this case, molecules) whose size is smaller than the wavelength of incident radiation. The atmosphere also contains particulates of various origins, both natural and anthropogenic. They too have a strong impact on solar radiation and climate through scattering and absorption. The size of these small particles, or aerosols as they are called now, varies widely according to their origin, but it is larger than the wavelength of incident radiation. For such a case, the theory proposed by Gustav Mie in 1908 needs to be applied to evaluate the aerosol extinction. Finally, the sky is frequently covered with clouds, which are made of liquid water droplets or ice crystals, depending on their altitude and other factors. Among all atmospheric constituents, clouds are normally those that have the largest impact on solar radiation, weather, and climate.

The unperturbed SSI that exists at about 100 km above the Earth's surface is progressively affected by all constituents just mentioned through absorption and

scattering along its path to the surface. Solar radiation that is reflected upward by the Earth's surface or atmosphere (clouds in particular) needs to be considered too. It participates to what is called the planetary albedo. Surface-reflected radiation is also a component of the total radiation incident on natural formations (e.g., mountain sides), human constructions (e.g., buildings or solar collectors), or living organisms (e.g., trees or standing humans).

Not all atmospheric gases are distributed vertically the same way. Some, such as oxygen (O_2), nitrogen (N_2), or carbon dioxide (CO_2) have a concentration (by volume) that is essentially constant with altitude. As a result, their total columnar amount above any given altitude is proportional to the atmospheric pressure at that level. Others, such as methane (CH_4), ozone (O_3), nitrogen dioxide (NO_2), carbon monoxide (CO), nitrous oxide (N_2O), or water vapor (H_2O) have intricate vertical profiles. Figure 3 shows such vertical profiles for different gases, as well as the main layers (troposphere, stratosphere, mesosphere, and thermosphere) as defined in the 1976 US Standard Atmosphere [27]. The temperature and gaseous profiles of this reference atmosphere, which is meant to be representative of typical "pristine" conditions at mid-latitude (45°N) locations, are widely used in idealized studies of radiative transfer. Whereas water vapor is most abundant in the lower troposphere, O_3 and NO_2 are concentrated in the mid-stratosphere, also known as the ozone layer, where NO_2 participates in the chain of chemical reactions that produce or destroy ozone,

Solar Radiation Spectrum. Figure 3
Vertical concentration profiles of some radiatively active gases in the US Standard Atmosphere of 1976

depending on temperature and abundance of other gases (such as chlorofluorocarbons). In the lower atmosphere around urban or industrial areas in particular, the concentration of O_3 and NO_2 may be considerably larger than indicated by the US Standard Atmosphere due to anthropogenic emissions and/or photochemical reactions. The other atmospheric constituents, for which reference atmospheres such as the US Standard Atmosphere do not provide a vertical profile, are those that are highly variable and not in gaseous state: aerosols and clouds.

Most clouds exist at an altitude below about 18 km above mean sea level. There are different types of clouds, and they are classified according to their form and height. Three layers are usually considered: low, middle and high. These correspond to cloud bases typically below 2 km, between 2 and 6 km, and above 6 km, respectively. To each layer (or "étage") correspond different cloud types (or "genera"). Normally, water clouds are concentrated in the two lower layers and ice clouds in the highest layer. Ice clouds are thin and therefore generally do not completely mask the sun. Water clouds are optically thicker so that their effect on solar radiation is considerable. The optical properties of clouds can be described in various ways. At the microphysical level, the concentration and size distribution of water droplets or ice crystals are necessary to calculate their bulk properties. When this information is not available, which is frequently the case, a convenient way to evaluate the overall optical properties of clouds is to use their fractional amount (the fraction of sky covered by the clouds) and their optical depth (or optical thickness), which both directly condition their radiative impact. A simplified cloud typology is provided in Table 1. For more details, see e.g., http://www.weatheronline.co.uk/reports/wxfacts/Cloud-classification.htm; http://en.wikipedia.org/wiki/International_Cloud_Atlas; and http://isccp.giss.nasa.gov/cloudtypes.html. Fog is a particular type of cloud whose base height is at surface level. It is normally reported as an obstruction to vision rather than as a cloud, hence it does not appear in Table 1.

Aerosols are particulates of various natural or anthropogenic origins: dust, salt, sand, smoke, pollutants, etc. Their size depends on their origin, and is highly variable, from about 0.01 to 100 μm. The size of hygroscopic aerosols (e.g., salt) also increases with

Solar Radiation Spectrum. Table 1 Classification of clouds and their optical depth

Level	Genera	Symbol	Base height (km)	Top pressure (hPa)	Optical depth
Low	Stratus	St	0.0–1.2	680	23–379
	Stratocumulus	Sc	0.3–2.0	680	3.6–23
	Cumulus	Cu	0.3–2.0	680	0.0–3.6
	Cumulonimbus	Cb	0.3–2.0	680	0.0–60
Middle	Nimbostratus	Ns	0–3	440	23–379
	Altostratus	As	2–6	440	3.6–23
	Altocumulus	Ac	2–6	440	0.0–3.6

relative humidity, particularly above 70%, or even more so, near saturation. Like for clouds, the microphysical properties (concentration and size distribution) of aerosols are necessary to evaluate their optical characteristics using first principles (Mie scattering theory). In practice however, bulk properties (such as spectral optical depth) are easier to obtain experimentally, and are therefore more readily available. Like water vapor, aerosols are concentrated in the lower troposphere, or mixing layer, within the first 2 km above the surface. Nevertheless, aerosol clouds originating from intense biomass fires or dust storms can be lifted to heights of 6 km or more, and can then travel over huge distances, up to thousands of kilometers, before dissipating (Fig. 4). Additionally, the concentration of aerosols in the lower stratosphere can be noticeable, due to meteoric dust and, more importantly, volcanic activity. In recent history for instance, the eruptions of El Chichón (1982) and Pinatubo (1991) sent aerosol clouds that circled the globe and had a profound impact on solar radiation transmission and climate in general. These effects leave their trace as sharp dips in solar transmission records, and can be felt during a few years after the eruption (Fig. 5).

Aerosols and clouds have strong direct effects on solar radiation transmission. Furthermore, they also interact through various physicochemical processes (e.g., cloud nucleation around aerosol particles), thus creating intricate indirect radiative effects, which are now known to affect climate. For instance, although aerosols tend to increase cloudiness, dark aerosols in smoke plumes from forest fires can actually prevent cloud formation.

Solar Geometry

Solar radiation transmission through the atmosphere – and by way of consequence, the planet's climate – is directly affected by the earth–sun geometry. Outside of

Solar Radiation Spectrum. Figure 5

Solar Radiation Spectrum. Figure 6
Solar geometry relative to a surface location, showing the solar zenith angle Z and the air mass m

the intertropical zone, the sun's position above the horizon is markedly lower in winter than in summer, which in turn is the cause of alternating seasonal differences in climate. The apparent position of the sun in the sky can be characterized by two angles, whose selection depends on the system of reference. The vertical position of the sun can be determined from the zenith through the zenith angle, Z, or with reference to the horizon with the solar elevation angle, H. These angles being obviously the complement of each other, the two reference systems are equivalent. However, the literature reveals that the use of Z is more frequent than that of H. The lateral position of the sun is characterized by its azimuth, ψ. It is usually measured clockwise from north. The vertical position of the sun is more critical than its lateral position since the former angle conditions the sun rays' pathlength through the atmosphere. The longer this pathlength, the higher the probability that solar photons will undergo some form of atmospheric extinction before hitting the surface. The optical mass of an atmospheric constituent, m, is defined as the ratio between a slant pathlength and a vertical pathlength for a zenith sun (Fig. 6). For a hypothetical plane-parallel atmosphere, one would have simply $m = 1/\cos Z$. Due to the atmosphere's sphericity, m does not reach an infinite value at sunrise or sunset. A precise evaluation of m as a function of Z is intricate since each atmospheric constituent has a specific vertical profile, while the refractive index is progressively varying along the path due to changes in pressure and temperature [28].

The optical air mass (or in short, "air mass"), m_R, is the optical mass corresponding to molecular (or Rayleigh) scattering. It is also the appropriate optical mass in calculations of absorption by uniformly mixed gases, such as CO_2 (Fig. 3). By extension, the air mass is frequently used to evaluate all possible extinctions, even though this is not strictly correct. In actuality, the optical mass of constituents that are concentrated at high altitude (such as ozone) is lower than the air mass, for any given $Z > 0°$. Reciprocally, the optical mass of constituents concentrated in the lower atmosphere (such as water vapor or aerosols) is larger than the air mass. However, such differences become only noticeable for Z larger than about 80° (Fig. 7). For applications where low-sun situations are frequent and accuracy is important, distinct optical masses for each extinction process should be considered. A set of fitting functions of Z has been proposed to obtain the optical mass of each significant extinction process as a function of Z [29, 30] thus advantageously replacing the repetitive and tedious calculations behind Fig. 7. Such optical mass calculations are accurate only to the extent that Z is itself obtained accurately. The ultimate accuracy requires Ephemeris-type calculations. Since these are impractical in most applications, various levels of simplification have been proposed in the literature, from sophisticated algorithms [31], methods of high accuracy but with efficient computational techniques [32, 33], and highly simplified equations that do not take long-term drifts in astronomical quantities or atmospheric refraction into consideration [34]. Typically, the former methods may be accurate to

Solar Radiation Spectrum. Figure 7
Optical masses for some atmospheric extinction processes

within about $\pm 0.001°$, whereas the latter equations are more in the $\pm 1°$ range, which may still be sufficient for engineering-type calculations. Online tools are also available. See, e.g., http://www.nrel.gov/midc/solpos/solpos.html http://www.esrl.noaa.gov/gmd/grad/solcalc/ http://solardat.uoregon.edu/SolarPositionCalculator.html http://www.volker-quaschning.de/datserv/sunpos/index_e.php.

In applications where solar radiation interacts with optical surface properties (reflection, absorption, or transmission), the angle of incidence, θ, of the sun rays on the surface must also be known. For a horizontal surface, θ is simply equal to Z. For incidence on a surface tilted at an angle s from the horizontal with an azimuth γ from north

$$\cos\theta = \cos s \cos Z + \sin s \sin Z \cos(\psi - \gamma). \quad (1)$$

Instrumentation and Units

Radiometry is the scientific field related to the measurement of electromagnetic radiation with radiometers. Spectroradiometry is the subfield that studies methods to measure spectral radiation with spectrometers or spectroradiometers – instruments that can discriminate narrow wavelength intervals. Photometry is the related field that involves the measurement of visible light by photometers that imitate the human eye's spectral response over the limited spectral band 360–830 nm. The fundamentals of radiometry and photometry are described in textbooks (e.g., [35]) or in online resources, such as http://www.optics.arizona.edu/Palmer/. Note that some confusion in terminology exists because astronomers tend to use the term "photometry" to refer to radiometry. An unfortunate consequence is that the astronomy-related science of studying radiometric quantities by pointing an instrument at the sun is still termed "sunphotometry," even though it does not involve the subjective perception of light by the human eye [36, 37]. The practical use of sunphotometers is discussed in section "Input Data to Radiative Model".

The measurement of spectral radiation involves a much more elaborate and costly experimental setup than what is needed to measure broadband irradiances with more conventional radiometers. Moreover, the absolute calibration of spectral radiometers is more challenging than that of broadband radiometers. Therefore, it must be borne in mind that the uncertainty in spectral measurements is usually larger than that in broadband measurements.

Although the measurement of spectral *radiance* is possible (to evaluate the variations in intensity and color over the sky vault, for instance), it is not common. Most experimental setups rather deal with the measurement of the spectrum directly emanating from the sun (direct irradiance), from the sky (diffuse irradiance), or from all possible directions (global irradiance). The SI unit for spectral irradiance, E_λ, is W m^{-3}, but it is most often reported in the more convenient units of W m^{-2} nm^{-1} (for wavelengths in nm) or W m^{-2} μm^{-1} (for wavelengths in μm). For some energy-related applications, such as photovoltaics, the quantum effect of photons needs to be characterized by the photon flux, F_λ, such that

$$F_\lambda = kE_\lambda \lambda/(hc) \quad (2)$$

where λ is wavelength, c is the speed of light in vacuum (2.99792458×10^8 m s^{-1}), h is the Planck constant ($6.62606896 \times 10^{-34}$ J s), and k is a numerical constant

used to reconcile units. It equals 1×10^{-13} for λ in nm, E_λ in W m^{-2} nm^{-1}, and F_λ in cm^{-2} s^{-1} nm^{-1}.

A similar conversion from energy to photonic units is used to study photosynthesis in many fields related to plant science. The *photosynthetically active radiation* (PAR) spectrum extends between about 400 and 700 nm. The correspondence between the spectral PAR irradiance in photonic units, P_λ, and its equivalent in energy units is obtained here as a slightly modified version of Eq. 2 [38]:

$$P_\lambda = E_\lambda \lambda / (N_A hc) \tag{3}$$

where N_A is Avogadro's constant ($6.02214179 \times 10^{23}$ mol^{-1}). (All physical constants used in this section are from CODATA 2006 [13], available from http://physics.nist.gov/cuu/Constants/papers.html.) Although PAR can be measured or modeled spectrally, only its integrated value over the PAR band is reported widely. This band-integrated quantity is measured either in energy units by a filtered radiometer, or in photon units by a quantum sensor, which is the preferred method. This defines the *photosynthetic photon flux density* (PPFD), usually expressed in μmol m^{-2} s^{-1}.

Throughout this section, the focus is on the part of the shortwave solar spectrum (from ≈300 to ≈4,000 nm) that can be measured from the Earth's surface. This includes the most energetic part of the spectrum (300–1,100 nm), which can be monitored with spectroradiometers equipped with a silicon (Si) detector. Such devices are fast, stable, well characterized and very common. For the near-infrared part of the spectrum between about 1 and 4 μm, other types of detectors become necessary, such as germanium (Ge), indium-gallium-arsenide (InGaAs), lead sulfide (PbS), or lead selenide (PbSe). Silicon photodiode arrays are increasingly used in spectroradiometers for their critical ability to sense the whole spectrum instantaneously over their spectral range. Instruments based on older types of designs have to progressively scan the spectrum, wavelength by wavelength, with an electromechanical system. This process can typically take a few seconds to a few minutes, which presents a difficulty since the sun and sky conditions may vary during that time. Spectroradiometers or sunphotometers that cover a very large wavelength range (e.g., 300–2,500 nm) must use at least two different types of detectors, making them more complex and expensive than instruments with silicon-only detectors. Other types of detectors and instruments are necessary to study the far-infrared spectrum (above ≈4 μm) that emanates from the sun, or is radiated upward and downward by the planetary surface–atmosphere system.

A spectroradiometer can be equipped with a flat diffuser to measure the global spectrum, or with a limiting tube (or collimator) to measure the direct spectrum. For continuous operation in the latter case, the instrument must be installed on a sun tracker. A temperature-controlled and weatherproof container is also needed for automated operation outdoors. Whereas laboratory instruments are sturdy, heavy, and need electricity, there are portable instruments specifically designed to operate autonomously in the field.

Like with any instrument, absolute accuracy, precision, resolution, and repeatability are important characteristics that contribute to the price of the instrument. Moreover, it needs to be frequently calibrated. This is usually accomplished in the laboratory with the help of a standard lamp (or with a calibrated lamp traceable to a standard lamp), whose spectral output is precisely known. Another technique, in the case of a spectroradiometer mounted on a tracker to measure the direct spectrum, is to use the sun as the source, through the "Langley plot" technique. This can be more accurate than the standard lamp technique, but has many limitations: it has to be done at a very clear site during very stable atmospheric conditions, wavelength by wavelength, and would not be advisable in the case of scanning instruments.

To compare a measured spectrum to a modeled spectrum, three characteristics of the instrument must be known: its spectral step, the shape of its filtering function (usually Gaussian or triangular), and its bandwidth. The latter is expressed as the full width at half maximum (FWHM). It is usually in the 0.5–5 nm range for good instruments, sometimes even less for instruments specifically designed for UV measurement (a lower value means a higher resolving power between one wavelength and the next). The FWHM may not be constant with wavelength, particularly with solid-state detector arrays. For instance, the FWHM of the Rotating Shadowband Spectroradiometer (RSS) varies from 0.3 nm in the UV to 3.9 nm in the near IR. The RSS is a particular type of instrument that records the global and diffuse spectra in alternation [39] and derives the

direct spectrum through Eq. 12 without the need for a collimator tube or tracking. Its sensor is a horizontal silicon array that is rapidly and alternatively unshaded and shaded from the sun with a little motorized shadowband.

Owing to the complexity and cost of monitoring the solar spectrum with instruments of dependable accuracy and reliability (especially in continuous operation under all-weather conditions), most spectral records are obtained at a few sites in the world for short experimental campaigns, or specific conditions (e.g., clear sky only). Long series of publicly available datasets providing quality-assessed data from various spectral instruments and ancillary meteorological data are extremely rare. It is worth mentioning the resources offered by the Atmospheric Radiation Measurement Program (http://www.arm.gov/instruments/location), the National Renewable Energy Laboratory (http://www.nrel.gov/midc/srrl_bms/; http://rredc.nrel.gov/solar/old_data/spectral/), and the NOAA-EPA Brewer Spectrophotometer UV and Ozone Network (NEUBrew, http://www.esrl.noaa.gov/gmd/grad/neubrew/). The latter is limited to the spectral range 286.5–363.0 nm for ultraviolet (UV) research, however.

Radiative Transfer Modeling

Considering the just-mentioned difficulties and cost of obtaining high-quality experimental data of spectral radiation, it is not surprising that modeling has become an essential tool to obtain spectral irradiance data. Based on the work of pioneers, such as Lord Rayleigh (1870s), Langley (1880s), Schuster (1905), Schwarzschild (1906, 1914), Mie (1908), or Eddington (1916), the field of radiative transfer modeling began to emerge in the 1940s under the impulse of astrophysicists, such as Chandrasekhar, who published *Radiative Transfer* – the first treatise on the topic – in 1950. (Incidentally, Subramanyan Chandrasekhar was awarded the Nobel Prize in Physics, 1983.) From then on, radiative transfer modeling became an essential tool in the hands of physicists, meteorologists, climatologists, energy engineers, etc. Recent textbooks on the topic should be consulted for current methodological and computational details [40–47].

In its basic form, the equation of radiative transfer simply expresses that a beam of radiation, initially of intensity (or radiance) I, that travels through any attenuating layer of thickness ds loses some energy through absorption, redistributes some energy through scattering, and gains another fraction of energy by emission, according to

$$dI_\lambda/ds = -\alpha_\lambda I_\lambda - \sigma_\lambda I_\lambda + B_\lambda \tag{4}$$

where α_λ and σ_λ are the absorption and scattering coefficients at wavelength λ, respectively, and B_λ is the emitted energy. By defining $k_\lambda = \alpha_\lambda + \sigma_\lambda$ as the total extinction coefficient and $k_\lambda\, ds = d\tau_s$ as the layer's total optical depth (due to both absorption and scattering), Eq. 3 becomes

$$dI_\lambda/d\tau_s = -I_\lambda + B_\lambda/k_\lambda. \tag{5}$$

Note that "optical depth" is also called "optical thickness." Emission only occurs in the far infrared, so that the last term can be ignored when dealing only with the solar (shortwave) domain. Still, the apparent simplicity of Eq. 5 hides the fact that all possible directions of propagation are involved, which precludes a simple algebraic resolution unless various simplifications are used. A highly effective simplification is to consider a plane-parallel atmosphere. Other simplifications are frequently used to specify the hemispherical directionality of σ_λ relative to the direction of propagation, which is defined by Z. For instance, for an ideally isotropic medium, σ_λ would be constant over all possible directions. Such a simple case never occurs in reality, however.

Using the popular *two-stream approximation*, it is possible to resolve Eq. 5 algebraically in the simplest way possible. This solution is fast and convenient, but its accuracy usually degrades noticeably when Z increases. More sophisticated solutions, such as the delta-Eddington approximation, the discrete-ordinate method, or purely numerical methods, are currently used in practice. Their features are compared in some textbooks [42, 47]. For optimal handling with modern computers, the models that allow the calculation of radiance and irradiance under various possible atmospheric conditions are packaged into Radiative Transfer (RT) codes. Most of them are not user friendly, and therefore require sufficient expertise to manipulate them correctly. A succinct description of some of these codes is available in textbooks (e.g., [30]) and online (http://www.statemaster.com/encyclopedia/

List-of-atmospheric-radiative-transfer-codes). RT codes are used routinely to solve various problems in atmospheric physics, including how the vertical irradiance profile varies with altitude over complex surface reflectance patterns [48].

In recent years, 3D radiative transfer modeling, using computationally intensive Monte Carlo codes (some of which are listed at http://i3rc.gsfc.nasa.gov/Public_codes_3DRT.htm), has gathered much interest to improve predictions of radiation transmission under complex conditions, such as cloud fields or surface reflectance properties with strong inhomogeneities [49–51]. An overview of the general principles of Monte Carlo modeling appears in [52]. Because of their importance in atmospheric sciences in general, and climate issues in particular, all types of RT codes are frequently intercompared by international teams for consistency and quality assurance [49, 53–56].

For engineering and other terrestrial applications, many more simplifications are desirable. They are motivated by various considerations: accuracy requirements are typically less stringent, results are needed fast, they often need to provide the irradiance incident on surfaces of various orientations (i.e., not just on the horizontal, as most atmospheric models are limited to), and, finally, intermediate results through the atmosphere (such as the vertical irradiance profiles) are superfluous, since only radiative results near the system being studied matter in this case. Many such simplified models have been proposed in the literature, to predict the spectral irradiance, and often also its integrated value over the whole shortwave spectrum, called broadband (or sometimes "total") irradiance. Spectral irradiance predictions can also be used to derive irradiances or photonic fluxes in narrower bands (e.g., photosynthetically active radiation, illuminance, or ultraviolet irradiance combined with any kind of action spectrum). Examples of spectral irradiance models for cloudless conditions include SPCTRAL2 [57] and SMARTS [29], whose codes are available online (http://rredc.nrel.gov/solar/models/spectral/; http://www.solarconsultingservices.com/smarts.php). In particular, SMARTS (Simple Model of the Atmospheric Radiative Transfer of Sunshine) has been thoroughly validated (e.g., [58, 59]), and is versatile enough to be used in a large variety of applications [60], such as the derivation of standard spectra (see Section Standard Spectra), the design optimization or power output simulation of photovoltaic (PV) or other solar energy systems [61–64], as well as the evaluation of the luminous efficacies of solar radiation under sunlight and daylight [65, 66]. To manage cloudy conditions, the simple empirical spectral cloud correction factors proposed for models such as BRGC [67] or SEDES2 [68] may be considered for very approximate results.

Direct, Diffuse, and Global Spectral Irradiance

Due to the more or less intense scattering effects that solar photons undergo while penetrating deeper through the atmosphere, solar radiation can exist in two different forms: direct, or "beam," radiation (directly emanating from the sun) and diffuse radiation (emanating from the rest of the sky hemisphere). Under clear skies, direct radiation is very intense and peaks at yellow to orange wavelengths (at noon and sunrise/sunset, respectively), while diffuse radiation is low and peaks at blue to violet wavelengths. Clouds tend to act as a neutral density filter, and therefore appear white or grey. Under overcast cloudiness, direct radiation disappears if the cloud is dense enough, and is then transformed into diffuse radiation, which is therefore normally more intense than under clear conditions. All kinds of intermediate situations may occur due to, e.g., haze (caused by aerosols) or partial cloudiness. Figure 8 provides a schematic representation of the main processes occurring in the atmosphere from the standpoint of a surface structure, such as a tree, a building, a solar system (as depicted here), etc. From this standpoint, three radiation components must be determined in most applications: the direct component from the sun, the diffuse component from the sky, and the diffuse component from surface reflections. The latter component is normally small, except in the case of a highly reflective ground (e.g., snow or white sand). Moreover, natural nondiffuse reflectors (such as water and ice at grazing angles) or man-made reflectors (glass, mirrors, and metals) may also add an intense direct (or "specular") component to the reflected radiation.

Since direct radiation propagates along only one direction, it is much easier to evaluate than diffuse radiation. Consider that direct radiation is attenuated along n different layers (or "slabs") of the atmosphere,

Solar Radiation Spectrum. Figure 8
Irradiance components relative to a tilted receiver

which may or may not be contiguous. From the Bouguer–Lambert–Beer law, the spectral transmittance, $T_{i\lambda}$, of the ith layer may be expressed by

$$T_{i\lambda} = \exp(-k_\lambda s_i) \tag{6}$$

where k_λ is an attenuation factor (due to scattering or absorption) for a single attenuation process per unit length, and s_i is the sun ray's pathlength through the layer. Assuming k_λ does not vary from one layer to the other, the total transmittance through the whole atmosphere is

$$T_\lambda = T_{1\lambda} T_{2\lambda} T_{3\lambda} \ldots T_{n\lambda} = \exp(-k_\lambda s) \tag{7}$$

where s is the total pathlength, i.e., the sum of all individual pathlengths s_i. This means that the order in which the layers are piled up has no effect on the result. Since s is difficult to measure in practice and the product $k_\lambda s$ is nondimensional, the latter can be advantageously replaced by the product of the air mass m (see Section Solar Geometry) and optical depth (or "optical thickness") at wavelength λ, τ_λ, which is to be evaluated along a vertical column above the point of interest (Fig. 4). The spectral transmittance at the bottom of the nth layer (e.g., at the Earth's surface) is then

$$T_\lambda = \exp(-m\tau_\lambda). \tag{8}$$

All atmospheric extinction processes $a, b, c \ldots p$ can be considered independently, each with a specific optical depth $\tau_{a\lambda}, \tau_{b\lambda}, \tau_{c\lambda}, \ldots \tau_{p\lambda}$, and transmittance $T_{a\lambda}, T_{b\lambda}, T_{c\lambda}, \ldots T_{p\lambda}$. Transmittances are multiplicative, so that the spectral irradiance at the bottom of the atmosphere, E_λ, can be expressed as

$$E_\lambda = T_{a\lambda} T_{b\lambda} T_{c\lambda} \ldots T_{p\lambda} E_{0\lambda} = T_{t\lambda} E_{0\lambda} \tag{9a}$$

or, equivalently,

$$E_\lambda = E_{0\lambda} \exp(-m\tau_{t\lambda}) = E_{0\lambda} \exp[-m(\tau_{a\lambda} + \tau_{b\lambda} + \tau_{c\lambda} + \ldots + \tau_{p\lambda})] \tag{9b}$$

where $E_{0\lambda}$ is the SSI, and $\tau_{t\lambda}$ is the total atmospheric optical depth. Since m is a pure geometric factor and $E_{0\lambda}$ is known from other sources, the only difficulty left in the prediction of E_λ is the evaluation of each individual optical depth at each wavelength.

For absorbing gases, τ_λ can be conveniently considered as the product of the total abundance of the gas along the vertical column, u, and its spectral absorption coefficient, α_λ. The latter is usually derived from spectroscopic measurements under well-controlled laboratory conditions. This simplified approach has been used in various engineering-type radiative models [57, 69], which have relatively coarse spectral resolution (typically 1–10 nm). The case of water vapor is the main exception to this rule and is much more difficult to handle accurately. High accuracies command the best possible spectral resolutions (with line-by-line data and codes) or "band-model" approximations derived from the latter.

For scattering processes by molecules and aerosols, the optical depth is still a convenient concept.

The optical depth for molecular scattering, $\tau_{R\lambda}$, decreases smoothly but strongly with wavelength (such as λ^{-4}) and can be derived from Rayleigh's theory. Different mathematical expressions, in the form of continuous functions of λ, have been proposed to simplify calculations while maintaining high accuracy. One such expression is used in SMARTS [30]:

$$\tau_{R\lambda} = (p/p_0)[117.3405\lambda^4 - 1.5107\lambda^2 + 0.017535 - 0.00087743\lambda^{-2}]^{-1} \quad (10)$$

where p is the actual site pressure, p_0 is standard pressure at sea level (1013.25 hPa), and λ is expressed in μm.

The aerosol optical depth (AOD; alternatively called "aerosol optical thickness," AOT), $\tau_{A\lambda}$, varies largely over space and time because it depends directly on both the quantity and type of aerosols, which are rapidly changing characteristics (see section "Input Data to Radiative Models" for sources of data). At wavelengths between about 350 and 1,000 nm – where the solar spectrum is most intense – the variation of AOD resembles that of $\tau_{R\lambda}$ albeit with a much flatter way, according to the empirical Ångström's law [70]:

$$\tau_{A\lambda} = \beta\lambda^{-\alpha} \quad (11)$$

where λ is expressed in μm, β is AOD at 1 μm, and α is the wavelength exponent, also called "Ångström coefficient," which varies usually between about 0.5 (for aerosols constituted of mostly large particles, such as from oceanic origin) to about 2.5 (for aerosols constituted of mostly fine particles, such as from urban origin). A typical average for rural-type aerosols, which are prevalently found in "clean" rural areas only subjected to local, natural aerosol sources, is 1–1.5. The value of β is site and time specific, and can vary from close to 0 at remote pristine sites (such as over mountain peaks) to 1 or more under extreme conditions, such as intense smoke from forest fires or dust storms around deserts. The measurement of α and β is discussed further in section "Input Data to Radiative Models". The extinction effect of aerosols is mostly in the form of scattering (with a strong forward scattering component), but some types of aerosols (particularly soot) can also absorb the incident radiation.

Finally, the cloud optical depth (COD) can be derived experimentally from spectral or broadband radiometric measurements, or can be derived from spaceborne sensor data using elaborate radiative-transfer calculations. COD can vary from less than 0.5 for very thin cirrus-type clouds to 100 or more for very thick and dark precipitation clouds (Table 1). As far as scattering is concerned, COD depends little on wavelength, and can therefore be approximated with Eq. 11 using $\alpha \approx 0$, so that COD values are usually quoted without a reference wavelength. However, clouds additionally exhibit strong absorption bands in the near infrared, due to their water content (liquid droplets or ice crystals).

Figure 9 compares the optical depths of the main extinction processes in the cloudless atmosphere, based on ideal conditions (such as USSA for the abundance of gases). The resulting individual transmittances for a zenith sun ($m = 1$) are illustrated in Fig. 10. It is obvious that wavelengths below 0.7 μm are dominated by scattering (with the exception of the UV below 0.35 μm, where ozone absorption is extremely strong), whereas the extinction at wavelengths above 0.7 μm is dominated by absorption.

When m increases, some extinction effects are exacerbated more than others. As a general rule, the extinction then increases relatively more at the shorter wavelengths than at the longer wavelengths, resulting in a red shift of the direct spectrum when the sun is low (explaining its reddish color at sunrise and sunset). This is illustrated in Fig. 11, which shows actual spectra measured under clear-sky summer conditions at the Solar Radiation Research Laboratory of Golden, Colorado (latitude 39.74°N, longitude 105.18°W, elevation 1829 m; data available online from http://www.nrel.gov/midc/srrl_bms). These direct irradiance spectra are measured automatically at 5-min intervals with a silicon-based spectroradiometer equipped with a tracker to follow the sun, and a collimator tube to block the radiation from the sky. With this arrangement, the sensor is continually facing the sun. Since the sun rays impinge on the sensor at normal incidence, what it measures is usually called direct normal irradiance (DNI), $E_{bn\lambda}$. Only a limited number of spectra are shown here (at uneven intervals) for legibility. Spectra measured under similar cloudless conditions, but for a winter day, are shown in Fig. 12.

The fraction of radiation that is scattered out of the direct beam is either lost to space (upward) or regained

Solar Radiation Spectrum. Figure 9
Optical depth of various atmospheric extinction processes for the conditions of the US Standard Atmosphere and various aerosol models, using SMARTS version 2.9.5

Solar Radiation Spectrum. Figure 10
Transmittance for the various extinction processes of Fig. 9 and an overhead sun ($Z = 0$ and $m = 1$), using SMARTS version 2.9.5

Solar Radiation Spectrum. Figure 11

Direct irradiance spectrum as measured automatically by a scanning spectroradiometer at Golden, Colorado, during a clear summer day. Not all recorded spectra are shown for clarity

(downward) as diffuse sky radiation. Since molecular scattering is most effective at short wavelengths, this downward diffuse radiation is characteristically blue rich, and even more so, ultraviolet rich. Below about 320 nm, where scattering is extremely intense, it is normal to find that the diffuse component is of comparable magnitude to – if not larger than – the direct beam component. Above that threshold wavelength, however, diffuse radiation is only a small part of the global spectrum, at least under clear skies with low to moderate AODs. Similarly to Figs. 11 and 12, Fig. 13 compares diffuse spectra measured at the Southern Great Plains experimental site (near Lamont, Oklahoma; latitude 36.61°N, longitude 97.49°W, elevation 310 m) of the Atmospheric Radiation Measurement program, at different times during May 2003. The instrument used here is an RSS, described previously in section "Instrumentation and Unit". The diffuse spectrum, $E_{d\lambda}$, is obtained when the shadowband blocks the sun. In the unshaded position, the global spectrum is rather obtained. This global irradiance, $E_{g\lambda}$, is the sum of the diffuse irradiance and the projected component of DNI on the horizontal, such as:

$$E_{g_\lambda} = E_{d\lambda} + E_{bn\lambda}\cos Z. \quad (12)$$

Under very clear conditions, $E_{g\lambda}$ is very close to ($E_{bn\lambda}$ cos$Z$) since the diffuse irradiance is small. Conversely, under a thick cloud cover, $E_{bn\lambda}$ becomes zero, so that $E_{g\lambda} = E_{d\lambda}$. More generally, the global irradiance below a uniform cloud cover, $E_{gc\lambda}$, can be estimated from that under similar cloudless conditions, $E_{g0\lambda}$, if the global transmittance of the cloud cover, $T_{gc\lambda}$, and the fractional cloud amount, C, are known, using the so-called independent column approximation [52]:

Solar Radiation Spectrum. Figure 12
Same as Fig. 11, but for a clear winter day

$$E_{gc_\lambda} = [CT_{gc_\lambda} + (1 - C)]E_{g0_\lambda}. \quad (13)$$

This approximation progressively deteriorates when Z increases under broken cloud conditions, because of shading and inter-reflections. An accurate solution would require 3D modeling in such a case. In the visible, $T_{gc\lambda}$ is mostly a function of COD and type of cloud (ice vs. water) for any specific Z. In the near-infrared, $T_{gc\lambda}$ is further reduced due to strong water (or ice) absorption bands, as shown in Fig. 14 for a few typical cases. Note that, for a specified COD, $T_{gc\lambda}$ is different for an ice cloud and a water cloud, even though their *direct* transmittance is essentially the same. The latter is not affected by absorption or wavelength, and can be approximated by $\exp(-m_c \bullet \mathrm{COD})$, from the Bouguer–Lambert–Beer law, where m_c is the cloud optical mass. Since the latter is difficult to calculate in practice, the optical air mass can be used instead, as a first approximation. No measurable direct radiation is transmitted when the product $m_c \bullet \mathrm{COD}$ is larger than about 5. The function $T_{gc\lambda}$ is calculated here with version 1.5b of the libRadtran RT code [71], which is publicly available online (http://www.libradtran.org). Another highly complex situation occurs whenever a realistic scene with more than one cloud layer must be modeled. Various approximation methods have been devised to provide a reasonable solution in such a case [72].

Figure 15 shows an example of comparison between the global, diffuse, and direct spectra predicted by SMARTS (using information on AOD and PW from a collocated sunphotometer) and the corresponding spectra measured by an RSS under clear-sky conditions. Since the model has a much higher spectral resolution than the instrument, the modeled spectra must be convolved with the spectral transfer function

Solar Radiation Spectrum. Figure 13
Diffuse spectral irradiance measured with a spectroradiometer under clear conditions in Oklahoma. Note the change of vertical scale compared to Figs. 11 and 12

of the instrument to simulate the smoothing effect of its bandwidth and provide a meaningful comparison.

For some applications, such as the performance simulation of flat-plate PV systems, it may be necessary to determine the global irradiance on a tilted surface. This "plane-of-array" irradiance, $E_{gs\lambda}$, must take into account the changes in geometry for both the direct and sky diffuse components, and the addition of reflected irradiance from the surroundings (natural environment, nearby constructions, boosting mirrors, etc.). This can be accomplished with Monte Carlo models, which can essentially handle any type of spatial environment and atmospheric conditions. However, their usage is complex, computationally intensive, and is generally too difficult or costly for nonexperts. Among the more conventional models, there are currently two radiative transfer models with such capabilities. SMARTS [58] can handle all possible tilt geometries, but it is limited to clear-sky conditions. Conversely, SEDES2 [68] can handle cloudy sky conditions, but only for surfaces tilted toward the equator, and with less spectral resolution and overall capabilities than SMARTS. Such calculations require some data on the spectral reflectance properties of all these intervening surfaces, which adds to the difficulty. In the absence of local reflectance measurements, SMARTS includes a library of spectral reflectance data for typical surfaces.

Input Data to Radiative Models

Although RT models are available to predict the components of solar irradiance under a variety of situations, they all need a variety of input data to describe the state of the atmosphere aloft. To obtain accurate

Solar Radiation Spectrum. Figure 14
Spectral transmittance for global irradiance under overcast conditions for various types of clouds, characterized by their optical depth (COD): thin ice cloud (COD = 0.5), thick ice cloud (COD = 5), thin water cloud (COD = 5), medium water cloud (COD = 10), and very thick water cloud (COD = 100). Calculations performed with libRadtran version 1.5b for an overhead sun (m = 1)

spectral irradiances, the difficulty is therefore twofold: the intricacies of the radiative model used must be understood, and the best input data for the cases under scrutiny must be obtained in detail (including appropriate time resolution, accuracy, and format), which is usually not a trivial task. Input data requirements differ from one model to the other, but there are general similarities. For instance, two completely different types of situations can be encountered depending on the problem at hand. The simplest possible case occurs when predetermined typical atmospheric conditions can be considered to obtain general "theoretical" results. A "model atmosphere" is then chosen by the user to represent the assumed average vertical profiles of all radiatively active atmospheric gases. Similarly, an "aerosol model" must be added since there are always some aerosols in the atmosphere, particularly in its lower layers. The only remaining variable is the apparent position of the sun. Such ideal situations are useful to develop parametric functions and explore "what if" scenarios.

A more difficult case arises when realistic atmospheric conditions must be simulated, such as for a specific location and time. The vertical profiles of gases and aerosols must then be obtained for this location and time, which usually requires precise specialized measurements. As a general statement, the accuracy in the predicted spectral irradiance (i.e., the model's output) depends on both the intrinsic performance of the model and on the quality of its input data. The spectral range and the spectral resolution are also elements to take into consideration. For instance, the total ozone amount conditions the ultraviolet spectrum, but has only a small impact in the visible or near-infrared (NIR) spectrum. Conversely, water vapor is a significant absorber in the NIR, but has no impact in the UV, and virtually none in the visible. Therefore, if only the visible spectrum is to be predicted, for instance, approximate determinations of ozone and water vapor can be tolerated.

From section "Direct, Diffuse, and Global Spectral Irradiance" and Fig. 10, it is obvious that, in general and over large spectral bands, there are three *variable* atmospheric constituents that influence the clear-sky shortwave spectrum most: ozone, water vapor, and aerosols. The most common sources of data for these constituents are reviewed next.

Ozone has been measured for decades from a world network of ground-based spectroradiometers called the World Ozone and Ultraviolet Radiation Data Centre (WOUDC; http://www.woudc.org/). The common unit for the vertical column amount of ozone is the Dobson Unit (DU), which commemorates the influential pioneering work of Gordon Dobson (1889–1976), who built the first instrument to measure ozone, known as the "Dobson spectrophotometer." One DU is equivalent to a depth of one hundredth of a millimeter along a vertical column maintained at standard pressure/temperature, i.e., 100 DU equals 1 atm-mm. The ozone amount typically varies day by day with a seasonal pattern, and is normally in the range 200–500 DU. Very low ozone amounts (<100 DU) are referred to as "ozone hole" conditions. Another source of ozone data, with better geographic coverage, but slightly lower accuracy, is from spaceborne sensors, such as TOMS, OMI, and SCIAMACHY (see, e.g., http://toms.gsfc.nasa.gov/teacher/ozone_overhead_v8.html and http://www.temis.nl/protocols/O3total.html). The vertical profile of ozone is measured by ozonesondes.

Solar Radiation Spectrum. Figure 15
Modeled global, direct, and diffuse spectra compared to their measured counterpart obtained with rotating shadowband spectroradiometer under clear skies in Oklahoma

Water vapor is also highly variable in both space and time. Contrarily to ozone, which is concentrated at high altitude, water vapor is concentrated in the boundary layer, up to 2–3 km above surface. Consequently, it is normal to observe very low water vapor amounts at elevated sites, such as mountain peaks and elevated plateaus. Moreover, there are seasonal variations (more water vapor in summer than winter), climatological variations (low water vapor in dry zones vs. high water vapor in humid tropical zones), and daily meteorological variations linked to the general circulation of air masses, cold fronts, etc. The vertical profile of water vapor concentration has been measured with radiosondes (or rawinsondes) for many decades. There are usually two ascents per day, at 0000 and 1200 Universal Time. Such data may be requested from each country's meteorological service, or obtained online from sites such as http://www.esrl.noaa.gov/raobs/. The total amount of water vapor is usually measured in terms of precipitable water (PW), also called "integrated water vapor (IWV)," which can be defined as the height that would occupy all the water vapor aloft if it were condensed inside a virtual vertical tube of 1 cm^2 section. This height is usually indicated in cm. Since 1 cm^3 of water weighs 1 gram, equivalent PW units are g/cm^3 or g/cm^2. (A better SI unit is kg/m^2, with 1 cm of precipitable water being equivalent to 10 kg/m^2.) Other ground-based determinations of PW can now be made by a variety of instruments, including special GPS sensors (see, e.g., http://www.suominet.ucar.edu/ and http://gpsmet.noaa.gov/jsp/index.jsp), sunphotometers (e.g., http://aeronet.gsfc.nasa.gov/), Fourier transform infrared spectrometers (FTIR), microwave radiometers (MWR), lidars, or millimeter-wave imaging radiometers (MIR). All these methods have upsides and downsides, and they are frequently compared and reviewed in the literature [73–76]. Some of these techniques also provide information on

the vertical distribution of water vapor. Other sources of data with a broader geographical coverage include spaceborne sensors (e.g., AMSU, AVHRR, GOME, MODIS, SEVIRI, SSM/I, or TOVS), datasets using assimilation of ground and satellite measurements such as NVAP [77], and reanalysis data [78–81].

Aerosol information is usually the most critical input, and yet the most difficult to obtain with good accuracy for a specific location and time. The recognized importance of local and global effects of aerosols in the current climate change research has led to considerable efforts being deployed to monitor their optical characteristics, particularly AOD. Four main methods are currently being used:

- Sunphotometry from ground sites, which can provide the spectral AOD after filtering of cloud occurrences, and by further derivation, the Ångström coefficient, the aerosols' single-scattering albedo (which characterizes their relative fraction of scattering and absorption), the phase function (which characterizes the directional scattering properties), and the size distribution of the particles in the vertical mix. The main world network is that of AERONET [82], http://aeronet.gsfc.nasa.gov/), but other, more limited, networks also exist (e.g., GAW, http://wdca.jrc.it/data/parameters/data_AOD.html, SKYNET, http://atmos.cr.chiba-u.ac.jp/index.html, and SURFRAD, http://www.srrb.noaa.gov/surfrad/aod/).
- Lidar measurements from ground sites, mostly used to evaluate the vertical profile of the aerosol concentration.
- Spectraradiometry from space platforms, with instruments such as MODIS and MISR. Since most of these satellites are polar orbiters, they cannot provide time-continuous AOD retrievals for any specific site, but they can accumulate long-term data series with good spatial resolution and provide useful aerosol climatologies over time. Because of the uncertainties in the measurements and retrieval algorithms, their AOD predictions must be validated against ground-truth data from ground-based sunphotometers.
- Chemical transport models, which predict the distribution of AOD over time and space by using source information about when and where natural or anthropogenic particles were released in the atmosphere, chemical information about their evolution and transformation, and meteorological information about the continuous movement of air masses. These models also need to be validated against ground truth [83]. The international Aerocom project (http://nansen.ipsl.jussieu.fr/AEROCOM/aerocomhome.html) has the mission to improve these models and facilitate their intercomparisons, or their comparisons with ground or satellite data.

Once AOD is obtained at various wavelengths, it is possible to extrapolate to other wavelengths through Eq. 11. For instance, most current AOD datasets derived from spaceborne sensors or chemical transport models report the AOD at 550 nm. Moreover, the Ångström turbidity coefficients α and β can be derived from such simultaneous measurements of $\tau_{A\lambda}$ at a few (usually 4–10) wavelengths $\lambda_0 \ldots \lambda_n$ by fitting these points to a linearized version of Eq. 11:

$$\ln(\tau_{A\lambda}) = \ln(\beta) - \alpha \ln(\lambda). \tag{14}$$

The intercept and slope of this fitted straight line provide $\ln(\beta)$ and α, respectively. The Ångström law expressed by Eqs. 11 or 14 is convenient and is observed to be of general validity in practice, although exceptions are possible and can be explained by theory [84, 85]. A few typical cases (for low to high turbidity) recorded with a sunphotometer equipped with eight AOD-dedicated filters appear in Fig. 16, which also shows variable curvature in the log-log plot of $\tau_{A\lambda} = f(\lambda)$.

Standard Spectra

The solar spectrum at the Earth's surface is variable in both space and time. Due to compensation effects, the direct and diffuse spectra are more variable than the global spectrum. Various physical, chemical, or biological processes are also dependent on the spectral distribution of incident radiation. In particular, scientists and engineers are confronted with determining the performance of PV devices that use solar cells, of spectrally selective fenestration used in energy-efficient buildings, or of natural daylighting systems. They also need to address how various materials degrade over time, due in part to the action of the UV spectrum.

Solar Radiation Spectrum. Figure 16
Variation of spectral aerosol optical depth with wavelength for selected measurements using a sunphotometer equipped with eight dedicated aerosol filters from 340 to 1,640 nm

All these applications rely on spectral information, and may require measured and/or modeled data. Such information may not be available at the design stage of an engineering project, however. In this case, the designer is interested in using reference spectral data. Moreover, when different products (such as PV panels or coated windows) must be compared or rated, some reference conditions must be agreed upon so that the performance of all competitive products can be evaluated fairly, using identical test conditions. These concerns have fueled the impetus to develop reference spectra for standardization purposes.

The American Society for Testing and Materials (now known as ASTM International) has proposed various standard reference spectra over the years. For space applications, their current standard is E490 [14]. For terrestrial applications, two older standard spectra [86, 87] are still referred to in the current literature or in other standards, even though they have been deprecated by ASTM and replaced in 2003 by their revised version, contained in a single standard, G173 [88]. One spectrum is for the shortwave direct irradiance. The other spectrum is for the shortwave global irradiance incident on a surface tilted at 37° toward the sun. Both are evaluated for clear-sky conditions at sea level for an air mass of 1.5 (i.e., a zenith angle of 48.24°), and for the whole spectral range (280–4,000 nm) covered by SMARTS. They integrate to 900 and 1,000 W/m^2, respectively. A slightly different version of G173's global spectrum has been adopted in 2008 by the International Electrotechnical Commission (IEC) for the testing of PV devices [89]. The justification and technical details behind the transition from the older spectra to the newer ones are detailed elsewhere [90, 91].

Recognizing the importance for users of these reference spectra to evaluate the possible effects of incremental changes in the spectrum on the performance of their systems, ASTM elevated SMARTS to the status of "adjunct standard" (ASTM reference: ADJG173CD). Although the spectra specially created by any user with this adjunct standard have no official validity, they are convenient since they are consistent with the

Solar Radiation Spectrum. Figure 17
(*Left*) Reference global spectra in the UV from ASTM G173 and G177. (*Right*) Direct, global, and diffuse reference spectra from ASTM G173 and G197. The G197 direct spectrum for a 20° tilt is not shown for clarity

reference spectra, and, most importantly, have the exact same spectral resolution. Using the same model for consistency, another global irradiance spectrum, limited to the UV spectral range (280–400 nm) and targeting material degradation applications, was also standardized to represent "high UV" and low air-mass conditions [92]. Finally, two direct irradiance spectra and two diffuse spectra for building and PV applications were standardized later, still using the G173 adjunct standard. These spectra correspond to the irradiance incident on either a vertical surface (representing a wall) or a 20°-tilted surface (representing a roof), and are directly compatible with those in G173 since they are for the same atmospheric conditions and same air mass of 1.5 [93]. A comparison of the current reference spectra is shown in Fig. 17.

Future Directions

Information on spectral solar radiation is available in different forms for many applications. The extraterrestrial spectrum and its short-term or long-term variations will continue to be improved from analysis of continuous spaceborne measurements. For terrestrial applications, spectral measurements are relatively scarce due to their initial cost, need for regular maintenance and specialized laboratory work for calibration. However, with appropriate weatherproofing, spectroradiometers can monitor the solar spectrum even under variable cloudiness, including precipitating conditions.

Solar spectra can alternatively be generated by radiative transfer models for a much lower cost, but they require specialized input data to represent the specific atmospheric conditions being modeled. Such data may be difficult to obtain without additional instrumentation, depending on the type of problem at hand. Research continues to improve the availability, accuracy, and resolution (both spatial and temporal) of the main atmospheric data that control the transfer of radiation: clouds, aerosols, water vapor, and ozone, most importantly. Improvements need to be done in different ways: additional networks of high-quality instrumented sites for continuous monitoring and ground truthing, deployment of more specialized spaceborne sensors, and development of high-resolution 3D models to predict and forecast the evolution of cloud and aerosol fields. Their integration with GIS tools would be extremely useful too.

If provided with accurate input data, the best models can predict accurate spectra, with an uncertainty similar to that of measurements under clear skies. Models also tend to have better spectral resolution and a larger spectral range than most instruments. Conversely, it might be extremely difficult to model the solar spectrum under rapidly changing cloudiness. Measurements have a definite advantage in this case. The current trend toward the development of compact, portable, low-cost, and easy-to-use solid-state spectrometers should continue, opening new windows of opportunities for the field of spectral measurement and radiometry, which is still mostly the realm of experts.

Finally, reference spectra have been standardized and are being used routinely in many engineering applications. New standards may have to be developed to accommodate the needs of emerging applications, such as concentrated PV or high-end daylighting devices.

Brightening Describes the evidence for a partial recovery from prior dimming at many locations between the 1980s and 2000.

Dimming Also known as "global dimming," a popular expression coined to describe the evidence for a widespread decline in surface solar radiation between the 1950s and 1980s.

Early brightening Describes the evidence for an increase in surface solar radiation during the 1930s and 1940s seen in the longest surface radiation records in Europe.

Pyranometer Measurement device to record the total flux (diffuse and direct) of solar radiation incident on a horizontal plane at the Earth surface.

Surface solar radiation Also known as "global radiation" or "surface insolation," refers to the solar radiation (sunlight) incident at the Earth's surface.

Definition of the Subject

Solar radiation incident at the Earth's surface is the ultimate energy source for life on the planet, and largely determines the climatic conditions of our habitats. The amount of solar energy reaching the surface is a major component of the surface energy balance and governs a large number of diverse surface processes, such as evaporation and associated hydrological components, snow and glacier melt, plant photosynthesis and related terrestrial carbon uptake, as well as the diurnal and seasonal course of surface temperatures.

It has also major practical implications, for example, for solar energy technologies and agricultural productivity. Changes in the amount of solar energy reaching the Earth's surface can therefore have profound environmental, societal, and economic implications. There is increasing evidence that the amount of solar radiation incident at the Earth's surface is not stable over the years but undergoes significant decadal variations. This entry discusses the evidence for these changes, their magnitude, their possible causes, their representation in climate models, and their potential implications for climate change.

Introduction

The major anthropogenic impact on climate occurs through a modification of the Earth radiation balance by changing the amount of greenhouse gases and aerosol in the atmosphere. The amount of solar radiation reaching the Earth surface is thereby particularly important as a driver of a variety of climate-relevant physical and chemical processes. Observational and modeling studies emerging in the past two decades suggest that surface solar radiation is not necessary constant on decadal timescales as often assumed for simplicity, but shows substantial decadal variations. Largely unnoticed over a decade or more, this phenomenon recently gained a rapid growth of attention under the popular expressions "global dimming" and "brightening," which refer to decadal decreases and increases in surface solar radiation, respectively. This is, for example, documented in a recent special issue in the *Journal of Geophysical Research* dedicated to the topic of global dimming and brightening [1].

Available Observational Data

Monitoring of surface radiative fluxes started in the early twentieth century at selected sites, predominantly measuring the downwelling solar component (also known as "global radiation," and referred to as surface solar radiation (SSR) in this chapter). For example, continuous measurements of SSR began in 1923 at the Stockholm observatory, and in 1937 at Potsdam (Fig. 1).

Solar Radiation Versus Climate Change. Figure 1
Annual mean surface solar radiation (in W m^{-2}) as observed at Potsdam, Germany, from 1937 to 2006. Five-year moving average in blue. Distinct phases of inclines (1930s–1940s, "early brightening"), declines (1950s–1980s, "dimming"), and renewed inclines (since 1980s, "brightening") can be seen

More widespread measurements of this quantity with thermopile pyranometers were initiated during the International Geophysical Year (IGY, 1957/1958). Many of these historic measurements have been compiled in the Global Energy Balance Archive (GEBA) at ETH Zürich [2, 3], and in the World Radiation Data Centre (WRDC) of the Main Geophysical Observatory in St. Petersburg, Russia. The data in GEBA underwent different quality checks to assure homogeneity in the records [3]. Homogeneous climatological records assert that any changes and variations in the data are induced by natural phenomena and are not an artifact. The accuracy of these historic measurements has been estimated in [3] at 2% on an annual basis. However, the quality of the measurements, performed predominantly under the auspices of the national weather services, is highly variable and not always well established. Rigorous quality control is necessary to avoid spurious trends in these data [3–5], and not all records are properly homogenized yet. In addition, possible "urbanization effects" in the surface solar radiation data [6] may have to be taken into account and need better quantification.

In the late 1980s the necessity for a reference network of surface radiation measurements with improved and defined accuracy was recognized. As a result, the Baseline Surface Radiation Network (BSRN) was established [7]. The first BSRN sites, equipped with instruments of the highest possible accuracy, became operational in the early 1990s. To date, more than 40 anchor sites in different climate regimes provide data at high temporal resolution (1-min data) for both solar (total, diffuse/direct, and reflected) and thermal (downward and upward) components. The BSRN accuracy targets are for surface solar radiation 2% or 5 W m^{-2} (ventilated pyranometer), for direct solar radiation 1% or 2 W m^{-2} (normal incidence pyrheliometer), for diffuse radiation 4% or 5 W m^{-2} (ventilated shaded pyranometer), for reflected SW radiation 5% (ventilated pyranometer), and for downward and upward thermal radiation ± 2 W m^{-2} (pyrgeometer). Other radiation networks with comparable quality standards were established around the world in recent years: the Atmospheric Radiation Measurement (ARM) Program with several worldwide distributed sites [8, 9], the SURFRAD (SURFace RADiation) network maintained by the National Oceanic and Atmospheric Administration (NOAA) with seven sites within the USA [10], the NOAA Earth System Research Laboratory (ESRL) Network with five worldwide distributed remote sites [4], the Australian Network maintained by the Bureau of Meteorology, and the Alpine Surface Radiation Budget network (ASRB) with seven sites in the Swiss Alps [11].

Despite the increasing number of high-accuracy surface radiation stations, large regions are insufficiently covered by direct surface radiation stations, such as vast areas of Africa, South America, and the Maritime Continent, and particularly ocean areas, which prevent a true global assessment.

Satellite-derived fluxes can provide a near-global picture, but their records are of limited lengths and go back to the early 1980s at most [12–14]. Furthermore, they do not directly measure the surface fluxes, but have to infer them from measurable top-of-atmosphere signals using, in addition, empirical or physical models to remove atmospheric perturbations. Satellite-inferred SSR records may also suffer from potential inhomogeneities due to changes in satellites, viewing geometries, inaccurate positioning, or sensor degradation, particularly in the earlier records [15].

In addition, reconstructions of SSR from more widely performed meteorological measurement quantities may be used to extend the information spatially and temporally, such as surface solar radiation changes inferred from observed changes in sunshine duration, diurnal temperature range, or pan evaporation [16–19].

Variations in Surface Solar Radiation

The earliest studies analyzing extended observational records of surface solar radiation appeared in the early 1990s [20–26] (see [27, 28] for a more complete overview). These pioneering studies presented the first evidence that solar radiation at the Earth's surface had not been constant over time as previously assumed, but showed significant decadal variations. Specifically, they pointed to declines in surface solar radiation since the 1950s in different regions of the globe. The first analyses with comprehensive datasets of sites distributed worldwide, as available from GEBA/WRDC, were performed by [3, 27, 29]. These studies reported an overall decrease of solar radiation at widespread locations over land surfaces on the order of 6–9 W m^{-2} between 1960 and 1990, corresponding to 4–6% over 30 years. The popular term "global dimming" was coined by Stanhill and Cohen (2001) [27] to describe this decrease. Increasing air pollution and associated increases in aerosol concentration have been suggested as major cause of this phenomenon, although changes in cloud amount and cloud optical properties may also contribute (see [28] for an overview). A direct assessment of the origins of surface solar dimming is complicated by the lack of adequate long-term observational datasets on variations of cloud and aerosol properties.

The studies on "global dimming" were all limited to data prior to 1990, since GEBA contained no data after 1990 at the time these studies were completed. More recently, ETH Zürich undertook a major effort to update the worldwide measured surface radiation data in GEBA for the period from 1990 to present. Wild et al. (2005) [30] evaluated the newly available surface observational records from GEBA and BSRN to investigate the trends in solar radiation in the more recent years. This analysis showed that the decline in solar radiation at land surfaces seen in earlier data is no longer visible in the 1990s at many locations. Instead, a brightening is observed since the late 1980s at the majority of the available observation sites (see also [28] for a recent review). A major exception is India, where the records show a persistent dimming throughout [30–32]. The brightening during the 1990s is not just found under all sky conditions, but also seen under clear skies at various sites, pointing to aerosol as a major cause of this trend reversal [28, 30, 33, 34]. The trend reversal is reconcilable with trends in aerosol emission, aerosol optical depth, and atmospheric transmission, which also show a distinct trend reversal during the 1980s [30, 35–39] (Fig. 2, taken from [30]). The trend reversal toward a reduction in aerosol emission and the associated increasing atmospheric transmission since the mid-1980s may be related to the adoption of more stringent air pollution regulations in developed countries, and the breakdown of the economy in the former communist countries. Changes in cloud properties also play a role in some regions and seem to be responsible, for example, for the dimming and brightening in New Zealand [40] and the recent brightening in the USA [41]. Overall, at many sites the brightening could not fully compensate for prior dimming, so that insolation levels around the year 2000 were still below those of the 1950s [28, 42].

The latest updates on solar radiation changes observed at the surface beyond the year 2000 suggest a continuation of the brightening at sites in Europe, in the USA, and in parts of Asia, particularly Korea [43]. Brightening seems to level off at sites in Japan and

Solar Radiation Versus Climate Change. Figure 2 Time series of annual mean atmospheric transmission under cloud-free conditions determined from pyrheliometer measurements at various sites in Russia (Moscow), Estonia (Tartu-Toravere and Tiirikoja), Switzerland (Payerne), and Japan (average of 14 sites) (From [30], online supporting material)

Antarctica after 2000, while indications for a renewed dimming are seen in China, likely associated with large emission increases in China after 2000. The compensating tendencies in various regions of the globe may tentatively indicate that the overall surface solar radiation signal inferred from ground-based observations did not undergo dramatic changes since 2000 [43]. This fits with the general picture provided by satellite observations, which suggest that the global mean planetary albedo as well as the background aerosol burden of the atmosphere may not have undergone substantial changes in the early 2000s, at least globally [37, 43, 44].

The longest direct observational records, which go back to the 1920s and 1930s at a few sites in Europe, further indicate some brightening tendencies during the first half of the twentieth century, known as "early brightening" [28, 45]. This suggests that dimming, at least in Europe, was restricted to a period between the 1950s and 1980s (see Fig. 1). A potential origin of this early brightening could have been the transition from the use of coal to oil as the main fossil energy source, which temporally reduced the emission of sulfur and black carbon [28, 46].

The early brightening up to the 1950s, the subsequent dimming until the 1980s, and the more recent brightening from the 1980s to 2000 are illustrated in the long-term solar radiation record measured at Potsdam (Fig. 1).

Climate-relevant surface radiative forcing is not only determined by surface solar radiation variations, but also strongly governed by the reduced thermal surface cooling with enhanced greenhouse capacity of the atmosphere, manifest in increased downward thermal radiation from the atmosphere to the surface. Compared to the solar component, much less information from direct observations is available on the temporal evolution of the downward thermal component. Operational monitoring of this quantity started in the 1990s in the abovementioned networks of BSRN, ARM, SURFRAD, and ASRB. The first analyses of the still very short time series of downward thermal radiation indicate an overall average increase in this quantity of 2–3 W m^{-2} per decade since the early 1990s at the globally distributed measurement sites of BSRN [47, 48]. Measurements taken in the Swiss Alps show an even larger increase in downward thermal radiation since 1995 in this particular region [11]. An increase in the downward thermal radiation is in line with the expectations from greenhouse theory and climate model scenarios [49], and gives direct evidence for the real existence of an increasing greenhouse effect [11].

Impacts on the Climate System

A growing number of studies provide evidence that the variations in SSR have a considerable impact on climate change. Wild et al. (2007) [42] investigated the impact of dimming and brightening on global warming. They presented evidence that surface solar dimming was effective in masking and suppressing greenhouse warming, but only up to 1980s, when dimming gradually transformed into brightening. Since then, the uncovered greenhouse effect reveals its full dimension, as manifested in a rapid temperature rise (+0.38°C per decade over land since mid-1980s). The early brightening may have contributed to the rapid warming during the 1930s and 1940s (Fig. 3, taken

Solar Radiation Versus Climate Change. Figure 3 Two-meter temperature anomalies over global land surfaces during the twentieth century. There is indication for a suppression of greenhouse-induced warming through "global dimming" between the 1950s and 1980s, and an enhancement through "brightening" between the 1920s and 1940s as well as from the 1980s onward. Anomalies are with respect to the twentieth-century average. Unit °C (From [28])

from [28]). Ruckstuhl et al. (2008) [50] and Philipona et al. (2009) [51] came to similar conclusions for the area of Europe, where brightening due to the substantial reduction in aerosol optical depth (up to 60% since 1986 at six remote locations in Europe) may have significantly contributed to the recent rapid warming in this region. Brightening, however, cannot supersede the greenhouse effect as main cause of global warming, since land temperatures increased by 0.8°C since 1960, even though solar brightening did not fully outweigh prior dimming over this period [42].

The climate models used in IPCC-AR4 do not seem to fully account for these observed decadal modulations of global warming through solar dimming and brightening, even if all known forcings are included in the models (Fig. 4) [52, 53]. They underestimate the suppression of warming through dimming between the 1950s and 1980s over global land surfaces, and simulate a higher rate of temperature rise than observed during this period (Fig. 4). On the other hand, for the more recent decades the models underestimate the rate of global warming, indicative of a lack of brightening (Fig. 4) [52]. The potential explanations that have been put forward for these modeling problems include the large uncertainties in historic emission inventories and associated aerosol burdens in the atmosphere, which may not consider the full extent of decadal variations, the inadequate representation of the direct and indirect aerosol forcings, as well as a general underestimation of the unforced natural variability in the models [52–54].

Wild et al. (2007) [42] provided further evidence for a strong impact of dimming and brightening on global warming, based on analyses of decadal changes in observed daily maximum and minimum temperatures and related diurnal temperature range (DTR). They found a slight decrease in the daily maximum temperatures over the "dimming" period from the 1960s to the 1980s, which is in line with the reduction of SSR over this period. Daily minimum temperatures, on the other hand, have been increasing over the same period, causing a decline in DTR. In contrast, since the mid-1980s, observed minimum and maximum temperatures increase at a very similar pace. This is indicative of a major change in the surface radiative forcing regime, where the maximum temperature rise is no longer suppressed as in the decades before, due to the transition from dimming to brightening [42]. The close correlation between DTR and SSR changes may also allow a reconstruction of SSR trends back to the first part of the twentieth century, when radiation measurements were lacking, but DTR observations were already abundant. This is at least feasible for the Northern Hemisphere with much more long-term observational temperature records than for the Southern Hemisphere (P. Jones, personal communication 2008). Figure 5 (taken from [28]) depicts the annual mean DTR evolution over Northern Hemisphere land surfaces during the twentieth century, as determined here from the CRU dataset. The figure not only suggests a downward tendency in DTR predominantly between the 1950s and 1980s and a leveling off thereafter as discussed above, but also a slight upward tendency in the 1930 and 1940s. This gives, on the one hand, support for two episodes of "brightening," one at the end of the twentieth century, and a second one in the 1930s and 1940s ("early brightening"). On the other hand, it implies that "global dimming" was essentially a phenomenon confined to about a 30–40 years period in the second half of the twentieth century [28]. This behavior is again not found in the IPCC-AR4 models [28].

Solar Radiation Versus Climate Change. Figure 4

Annual mean temperature anomalies (°C) over land surfaces from 1958 to 1999, as simulated by 18 Global Climate Models in "all forcings" twentieth-century experiments performed for the Fourth IPCC assessment report (*left panel*), and as observed (*right panel*). Multimodel mean given as thick black lines. Individual model realizations shown as dashed lines. Linear regressions for the periods 1958–1985 in blue and 1985–1999 in red. Observations from the CRU dataset [60]. Reference period for anomalies is the entire twentieth century (From [52])

Solar Radiation Versus Climate Change. Figure 5

Annual mean diurnal temperature range (°C) anomalies averaged over Northern Hemispheric land surfaces, from 1900 to 2002. Variations of diurnal temperature range may provide a useful proxy for variations in surface solar radiation. Data from CRU [60]. Anomalies are shown with respect to the 1961–1990 mean (From [28])

Solar energy available at the earth's surface is also a major determinant of surface evaporation and thereby the main driver of the global water cycle. Wild et al. (2004) [55] suggested that surface solar energy reductions outweighed the increasing thermal energy from the greenhouse effect from the 1960s to 1980s, resulting in a reduction of surface net radiation and associated evaporation over land surfaces, causing an attenuation of the intensity of the associated hydrological cycle (Fig. 6). In contrast, for the more recent period 1980s to 2000, Wild et al. (2008) [48] pointed out that the surface solar brightening adds to the increasing energy from the enhanced greenhouse effect, leading to higher evaporation and an intensification of the global terrestrial water cycle since the 1980s (Fig. 6). Again, current climate models are not capable of adequately reproducing these decadal variations in the hydrological cycle [28, 56]. Robock and Li (2006) [57] used the dimming phenomenon to explain the increasing soil moisture and decreasing evaporation between the 1960s and 1980s, as seen in long-term soil moisture records in the Ukraine. Impacts of the transition from dimming to brightening can further be seen in the more rapid retreats of glaciers and snow cover, which became evident since the 1980s as soon as the dimming disappeared [28, 58].

There are also indications that dimming and brightening may impact the terrestrial carbon cycle

Solar Radiation Versus Climate Change. Figure 6
Northern Hemispheric terrestrial precipitation anomalies (in mm) during the second half of the twentieth century. During the "dimming" phase (1950s–1980s), the decline in downwelling solar radiation may have outweighed increasing downwelling thermal radiation from enhanced greenhouse gases, and thereby reduced the surface net radiation, causing reductions in evaporation and associated intensity of the hydrological cycle. During the "brightening" phase (1980s–2000), the disappearance of the dimming no longer compensated for the enhanced greenhouse effect, leading to an increase in surface net radiation and an intensification of the hydrological cycle. Data from the Global Historic Climate Network (GHCN)

and plant growth [59]. During dimming, plant photosynthesis and associated terrestrial carbon uptake might have been enhanced despite a reduction in surface solar radiation, since the stronger aerosol and cloud scattering increased the diffuse radiative fraction during this period. Diffuse light penetrates deeper into the vegetation canopies than the direct sunbeam and can therefore be more effectively used by plants for photosynthesis. The modeling results of this study suggests that the effect of the increasing diffuse fraction dominates over the reduced surface solar radiation during dimming, leading to an enhanced terrestrial carbon uptake in this period, which fades thereafter during the brightening period with declining diffuse fraction [59].

Further research will be required to establish the full dimension of impacts of surface solar dimming and brightening on the climate system and climate change.

Future Directions

To the extent that decadal variations in surface solar radiation are caused by anthropogenic air pollution, dimming and brightening will depend on future anthropogenic emissions of aerosols and aerosol precursors [28]. These emissions may change substantially in the future in response to economic growth, energy consumption, and air pollution regulations. The tendency toward a renewed dimming seen in the radiation data in China since 2000, for example, is not unexpected, because coal consumption in China has doubled between 2002 and 2007 (data available from the US Energy Information Administration) [28]. On the other hand, not much further brightening might be expected in Western industrialized countries, since aerosol levels stabilized since about 2000 at low values [36, 51]. A renewed overall dimming can therefore not be excluded for a few years to come, with the air pollution mitigation potential approaching saturation in many of the industrialized nations on the one hand, thus preventing further policy-related brightening, and continued increase of air pollution and associated dimming in developing and emerging nations on the other hand. This could also have implications for the near-term global warming. However, such a potential renewed dimming clearly should not be persistent, as in developing countries as well as in East Asia and India, new air pollution regulations will become

inevitable to prevent drastic health or environmental problems. Therefore, in the longer run, a turn into brightening can be expected also in these countries. Under these perspectives, effective greenhouse gas mitigation measures call for urgent implementation to prevent drastic temperature rise under foreseeable future brightening.

The continuation of accurate monitoring from both surface and space, along with the development of advanced global modeling systems, will be of utmost importance to diagnose, understand, and control these anticipated fundamental changes in the radiation balance of the globe.

Solar Radiation and Sustainability

Solar radiation is ultimately what directly brings two essential conditions that are needed to maintain life on Earth: light and heat. Light is obviously what is most directly needed by photosynthesis to absorb carbon dioxide and produce oxygen. Indirectly, various chemical reactions in the atmosphere induced by solar radiation – particularly in the ultraviolet (UV) – produce some critical elements (such as ozone and oxygen) in the right quantities and at the right altitude. The result of these direct and indirect effects is to maintain atmospheric gases to levels compatible with life as it is known. By extension, the quantity and quality of solar radiation is what totally determines the delicate balance of the Earth's ecosystems, the agricultural and forestry resources needed for human or animal food, and even the development of our civilizations.

In the present era, various factors are contributing to a stronger-than-ever need for a detailed understanding of how constant the sun's energy output is, how it propagates through the Earth's atmosphere, how its local or global variations affect our climate and life forms (including human health and behavior), how human activities induce changes in solar radiation as well as climate, and how or where it can be efficiently harnessed to develop advanced solar technologies. Such "clean" technologies are particularly necessary today to solve three critical and interrelated problems of our industrial civilization: climate change, pollution, and near complete dependence on nonrenewable energy sources. The latter factor is a major cause of the two others, and all three are fundamental reasons why our current civilization is *not* sustainable. The societies of the future will need to be based on a zero-emission renewable energy economy. This is a necessary (but not sufficient) condition to achieve sustainability.

Historical Perspective

Interest for solar radiation, and solar energy applications in general, is not new. Many textbooks or other sources provide historical accounts of discoveries or technological breakthroughs from some solar pioneers since the Antiquity. One barely known pioneer was Frank Schuman (1862–1918), an American engineer who developed various solar thermal engines that could produce steam. These were similar to those that are currently being developed throughout the world with a technology known as Concentrating Solar Power (CSP), which uses parabolic troughs (or other concentrating devices) to heat a fluid, produce steam, and ultimately electricity. Unfortunately, Schuman's inventions, and even a full-scale 88-kW demonstration plant in Egypt, progressively fell into oblivion while the reign of cheap oil was starting. Schuman was not just an engineer, but also a visionary, as exemplified by this surprising statement of his: "*One thing I feel sure of. . . is*

that the human race must finally utilize direct sun power or revert to barbarism" [1]. Although this doom's day scenario might sound extreme or utterly simplistic, there is some truth in this 100-year old warning. A more balanced and science-based statement could be "Since it is a finite system, the technological human civilization must only utilize renewable sources of energy, maintain its expansion below the limit of the Earth's 'carrying capacity' or 'planetary boundary,' and maintain sustainability for all aspects of life in that system, or eventually disappear."

In more recent history, the last 4 decades have seen considerable developments in the field of solar radiation. In the early 1970s, the oil embargo crisis sprung interest for alternative energy sources, such as solar, as well as sustainable architecture (then known as "passive solar" or "bioclimatic" architecture). Solar radiation models were developed to provide engineers and architects with modeled solar radiation data, which were necessary because very few meteorological stations were measuring it over the world. The political support for the development of solar energy applications was short-lived, unfortunately, but the field of solar radiation modeling and measurement for energy applications remained relatively active. In recent years, the interest for renewable energy applications surged again, as an anticipated way of curbing climate change, and also as a way to decrease dependence on fossil energy sources, which are not as cheap now as they were before.

Still in the 1970s, the discovery that anthropogenic emissions of halocarbons were a threat to the ozone layer [2] generated considerable interest for the study of ultraviolet radiation (UV). The main orientations of these studies were: the relationship between ozone and UV, the geographic, historic, and projected variations in the quantity and spectral quality of UV, its effect on the ecosystem and various food chains, and its effect on human health. By the mid-2000s, the halocarbon concentrations had considerably decreased, as a direct effect of the Montreal protocol. There were indications that the ozone layer had stopped its decline, and might even show the first signs of recovery [3]. This slowed down the research on UV, although new topics of interest surfaced. For instance, there is now less emphasis on the erythema and other negative health effects of UV (e.g., skin cancer), but there is more interest for the positive side of it, particularly the synthesis of vitamin D.

The 1970s also saw the developing awareness of what was originally called "global warming" [5], but is now more generally referred to as "climate change." Since solar radiation is the most important source of *natural* heating of the atmosphere, it is obvious that the whole field of climate change is directly dependent on a better understanding of the transfer of solar radiation through the atmosphere. Rapid progress followed in various areas of research: radiative transfer modeling, remote sensing of atmospheric constituents using ground-based or satellite-based instruments, improved measurements of solar radiation both outside of the atmosphere (with satellite-based sensors) and at surface level (with ground instruments using advanced radiometric methods), and evaluation of solar radiation on a global scale based on satellite-based observations. In 2005, the national science academies of the G8 nations and Brazil, China, and India signed a statement on the global response to climate change. One of the recommendations of this statement was "Show leadership in developing and deploying clean energy technologies and approaches to energy efficiency, and share this knowledge with all other nations." In 2007, the Intergovernmental Panel on Climate Change (IPCC), Nobel Peace Prize co-awardee that year, published its fourth assessment report [6], which introduced the notion that renewable sources of energy would have an important role to mitigate climate change. The report also contained an entire chapter dedicated to the importance of sustainable development. Then, in 2011, the IPCC published a special report on the role of renewable energy sources, again for the mitigation of climate change [7], providing more coverage of the role of renewable energy than was included in the 2007 report [6], as well as a stronger push for appropriate renewable energy policies.

All these important developments are obvious indicators that the study of solar radiation (in a broad sense) is now central to the very sustainability of our civilization, and is thus more important than ever. Throughout this entry (13 articles), the term "solar radiation" generally refers to electromagnetic radiation at wavelengths shorter than about 4 μm, which contains most of the solar spectrum's total energy. This is also referred to as "shortwave radiation" in the literature. In contrast, the "longwave radiation" from the sun (beyond 4 μm, i.e., in the infrared region of the

spectrum) is relatively weak, so that the thermal emission from the Earth's surface is of similar magnitude. A large part of the global warming process is caused by the blanketing action of the so-called greenhouse gases, which tend to decrease the thermal (or longwave) radiation emitted to space, and thus the natural cooling of the Earth's surface and its lower atmosphere. Since the longwave part of the solar spectrum is of too small magnitude to be of direct use in the context of sustainable technologies, only the shortwave part of the spectrum is investigated here.

Multidisciplinary Perspective

As can be understood from the above discussion, there are many disciplines directly or indirectly related to solar radiation. Essentially, all of them can now benefit from recent advances in remote sensing, particularly from satellites. Satellite-based information brings large geographical coverage at continuously improving spatial and temporal resolutions. Among other things, the retrieved variables include the solar radiative output, various atmospheric constituents (e.g., ozone, water vapor, aerosols, clouds), surface reflectance and land use, temperature and precipitation, and various components of solar radiation incident on the Earth surface.

It is logical to start the study of solar radiation by characterizing the solar radiative output, in terms of both its total radiative power and its spectral distribution (see ► Solar Constant and Total Solar Irradiance Variations and ► Solar Radiation Spectrum). Since these articles were written, new and important progress has been made in the measurement of the total radiative output of the sun, now referred to as *Total Solar Irradiance* (TSI). Validation of the recent results from the SORCE satellite mission indicated that the previous satellite-based determinations of TSI were too high. This important development may have implications in many disciplines, such as climate change [8]. The PREMOS instrument on the PICARD satellite (launched June 15, 2010) is the first space radiometer with a calibration that is fully traceable to SI, and with an extremely low uncertainty (0.05%) compared to ground-based field instruments (1–5%). The PREMOS observations have the potential to resolve the disagreement on the absolute value of TSI that followed the introduction of the SORCE data in mid-2003. Based on the preliminary PREMOS data available as of this writing (November 2011), and their comparison with other sources of longer duration (including SORCE), the long-term average value of TSI (referred to as the "solar constant" in the past) would be about 1361.2 W m^{-2}, which is $\approx$5 W m^{-2} lower than previous determinations (e.g., [9]).

Variations in the solar output and its spectral distribution have a direct effect on climate (see ► Solar-induced Climate Effects and ► Solar Radiation Versus Climate Change). In recent years, the quiet period between the sun's Cycles 23 and 24 appeared much longer than usual. Since low solar activity normally corresponds to a lower TSI and much lower UV or extreme UV (which affect the upper terrestrial atmosphere), there were concerns about a possible "Little Ice Age" syndrome, which obviously would have directly affected our lives. New research [10] shows that the radiative forcing of climate from solar origin is not necessarily in phase with solar activity in the ultraviolet (UV), as was generally considered before. The sun-climate relationship is complex, but ultimately, the sustainability of our civilization depends on the sun not being too variable. Studies of the propagation of UV radiation through the atmosphere, and of its fraction reaching the surface, in relation with variations in the ozone layer and with climate change, are important to many aspects of life on Earth, including human health (see ► Ultraviolet Radiation: Distribution and Variability, ► UV Effects on Living Organisms, and ► Solar Radiation and Human Health). Daylight is another aspect of solar radiation that affects human health and behavior. Thus, natural illumination is also an essential component of the good design of energy-efficient buildings, which is a key aspect of sustainable architecture (see ► Daylight, Indoor Illumination, and Human Behavior).

The fraction of solar radiation that is directly used by plants for photosynthesis also needs to be studied to better understand the potential of plant production (in agriculture and forestry) and their indirect effect on climate (through absorption of carbon dioxide in particular). It is obvious that appropriate food production is essential to guarantee the sustainability of our civilization (see ► Photosynthetically Active Radiation: Measurement and Modeling).

The most direct link between solar radiation and sustainability science and technology remains the utilization of solar radiation as a source of "clean" energy. Considerable developments in this direction have been made in the last few years, for reasons explained above. The early developments in solar energy (from the early 1970s to the late 1990s) were focused around small systems for the heating of residences (passive solar architecture) or the heating of water with solar collectors. Then the photovoltaic (PV) revolution started, fueled by the rapidly decreasing price and increasing availability of such systems. Mass production and still decreasing costs now make this technology appealing to the power industry and electric utilities as well. The size of solar projects thus rapidly increased from a few kilowatts to multi-megawatts in a matter of a few years. Other large solar systems use concentrators, either to heat a fluid and produce electric power with a turbine (the CSP path) or to use high-efficiency PV cells for the direct production of electricity (the CPV path).

The considerable costs of large projects force them to obey the bankability rules of financial institutions. The revenue from a solar power plant is essentially proportional to the local solar resource. The field of *solar resource assessment* thus rapidly became an important component of the whole financing process. It consists of an analysis of the local solar resource, in terms of magnitude, variability and risk assessment of "bad years," and the production of a dataset of solar radiation and important meteorological variables (temperature, precipitation and wind speed, in particular) covering a period of at least 10 years with a time step of 1 h or shorter. The development of such data series is based on radiative models using satellite-derived observations and/or on local radiometric/weather measurements (see ► Solar Irradiance, Global Distribution, ► Solar Radiation for Solar Energy Utilization, and ► Topographic Solar Radiation Modeling for Environmental Applications).

Spatial and temporal variability is another important factor here. Spatial variability conditions the confidence that analysts can have in spatial extrapolations of solar radiation data, which is often necessary. Short-term temporal variability (at a time scale of seconds to minutes) is of interest to CSP operators (to optimize the use of heat storage, if available), and to electric utilities (to study the impact of intermittent electric production on the stability of the electric grid). Long-term temporal variability (at a time scale of days to years) is a key aspect of solar resource assessment (see ► Solar Radiation, Spatial and Temporal Variability).

Various solar technologies (such as PV) or building technologies (such as energy-efficient glazings) employ materials that are spectrally selective, that is, whose response depends on wavelength. Similarly, most materials degrade over time when exposed to sunlight, and this process is spectrally selective too. For such applications, detailed knowledge of the spectral distribution of solar radiation and its variations over time is necessary. This can be obtained by radiative modeling, measurement, or their appropriate combination (see ► Solar Radiation Spectrum).

Finally, the field of *solar radiation forecasting* is still in its infancy, and thus is not covered here. It combines solar radiation modeling with advanced numerical weather prediction techniques used in meteorology and/or statistical techniques [11–16]. Rapid developments are expected in the near future, for instance, to help electric utilities improve the management of their solar power plants, or prepare optimal schedules for the use of storage or reserves in anticipation of cloudy periods.

Autocorrelation The autocorrelation of a random process describes the statistical analogy between values of the process at different points in time, as a function of the two times or of the time difference.

Clearness index Ratio of the global irradiance on a horizontal plane (on the earth surface) to the respective irradiance just outside of the atmosphere.

Clear-sky index Ratio of the global irradiance on a horizontal plane to the irradiance expected under clear-sky conditions.

DNI Direct normal irradiance.

GHI Global horizontal irradiance.

Ground albedo Measure of how strongly the ground reflects sunlight.

Residual time series A time series in which the trends have been removed.

Definition of the Subject

Solar irradiance is a highly variable and fluctuating resource. This characteristic directly and strongly affects the performance of solar energy systems, such as the electricity production from photovoltaic (PV) systems or solar thermal power plants. This entry describes databases and appropriate methods to characterize spatial and temporal variability in solar radiation. The regional distribution of solar energy depends on the meteorological situation characterized by clouds, aerosols, and water vapor content, but also on topography and ground albedo. Within this entry the focus is laid on cloud-induced fluctuations. The spatial variability caused by the topography of the terrain is not accounted for here, since it is the topic of another entry in this encyclopedia.

Introduction

As fluctuations in solar radiation are directly coupled to the output power and yield of a grid-connected PV system, for instance, efforts have been taken to measure and characterize the solar resource's spatial and temporal variability. At first, studies focused on the impact of temporal variations. With the growing PV market and

ever increasing amounts of PV power fed into the utility grid since the early 1990s, studies of the spatial characterization of solar radiation became necessary.

Spatial variability of the solar radiation field may influence the performance of a distributed solar energy system in two ways. The collection of solar energy at different points in space leads to a smoothing of temporal fluctuations in the overall solar energy input and thus in the total power output. On one hand, this smoothing is beneficial to the system's performance, while on the other hand it must be assured that local differences in energy flow can be handled by the power distribution network.

For systems distributed over a small area only, in general the spatial variability of high temporal resolution data (with samples taken every minute, or even every second) needs to be accounted for so as to fully characterize the power fluctuations. If large-scale systems, such as grid-connected PV systems that are scattered over the whole area of a large-scale utility network, are analyzed the investigation of the temporal structure of the irradiance field with a coarser temporal resolution is adequate. Hourly data can be used in this case.

This entry gives a summary on appropriate methods to characterize the spatial and temporal variability in solar radiation. An overview about databases and methods proposed by different authors is given.

The variations of solar radiation are studied with respect to time and location. As long as the temporal and regional evolutions are controlled by temporal and spatial correlation structures, common tools in statistical analysis of time series can be applied. Other methods model the cloud field structures that induce fluctuations in solar radiation on small scales. For larger scales, satellite data have been used.

Examples for Spatial and Temporal Variability on Different Scales

This section is meant to provide a sense of the temporal and spatial variability of solar radiation, using 1 year of modelled radiation data in Germany as an example. The temporal variability induced by cloudiness is analyzed on different timescales.

Figure 1 shows the variability of daily irradiance sums and their monthly averages at three sites in Germany for the year 2009. The data has been derived from satellite images of Meteosat Second Generation with the Heliosat method [1]. Seasonal variations of the monthly averages are mainly caused by the varying position of the earth's polar axis with respect to the sun. For sites in Northern Germany with a distance of 55 km this annual course and the daily values are closely related but not identical. The Southern site lies at a distance of more than 600 km; the annual course shows similar seasons but with notable differences compared to the Northern sites. All sites show considerable fluctuations of the daily sums of irradiance around the monthly average values.

The variability within a day and from site to site is exemplified in Fig. 2. Hourly values of global horizontal irradiance (GHI) are shown for 15 days in May 2009 and for seven German sites. The obvious day/night pattern is deterministic; its annual and daily variations can be described by analytic models of the sun–earth geometry. Other differences in the time series are caused by clouds; their occurrence is of a stochastic, rather than deterministic, nature.

The temporal variability within a day is given in more detail in Fig. 3. This example of minute-by-minute values shows that the passing of a field of opaque clouds may lead to changes of the incoming irradiance of up to ~80% of the clear-sky value within a minute. For a proper analysis of these fluctuations, it is reasonable to separate the deterministic annual and daily trends from the stochastic variability of the atmospheric conditions.

Information about the interannual variability of GHI can only be obtained with long-term data. An example for the interannual variability is shown in Fig. 4 for monthly sums of GHI. Here, for two Italian sites, the satellite-derived averages, maxima and minima within a 15-year period are compared to ground-measured averages (climate normals) of a disjoint 30-year period. For these sites the long-term averages are similar for both sources with relative deviations within ±10% for Torino and ±4% for Brindisi. The monthly sum of an individual year can strongly deviate from the long-term average by ±30% for Torino and ±20% for Brindisi.

Databases for the Statistical Analysis of Solar Radiation

The meteorological services of most countries operate a network for solar radiation. For instance, the German

One year of daily sums of satellite-derived global horizontal irradiance, GHI for three German sites in comparison to the monthly average of daily sum. *Upper image*: two sites in North Germany with a distance of 55 km (blue Neuhaus/Oste, 53.8034°N, 9.0027°E, red Nesserdeich, 54.3139°N, 9.0027°E). *Lower image*: one site in North Germany (blue Neuhaus/Oste), one in South Germany (red Lengenfeld, 48.0745°N, 9.0045°E), distance 633 km

service (Deutscher Wetterdienst, or DWD) monitors GHI at about 50 stations with interstation distances of 25–800 km. Usually the data are made available as hourly averages.

The analysis of the structure of the irradiance field over smaller spatial distances has to rely on networks that are specially designed for this purpose. The first measurement campaigns of this kind have been reported in [2, 3]. A network of 11 pyranometers distributed across an area of 75×75 km^2 in Pennsylvania was operated during 2 weeks collecting 1-min averages of GHI [4]. In Scotland, data have been recorded in the Pentland Hills (1987–1989, 10-min averages) and Edinburgh (1993–1995, 30-s averages) within an area of 10×30 km^2 [5]. A similar network of ten stations has been operated at Saarbrücken, Germany. Here, 10-min averages of GHI have been recorded for 1.5 years [6].

Mesoscale and small-scale networks had been installed by University of Oldenburg. The irradiance on horizontal and inclined planes was recorded with a temporal resolution of 10 s at five stations [7]. During

Solar Radiation, Spatial and Temporal Variability. Figure 2
Satellite-derived hourly global horizontal irradiance for 15 days of May 2009 for seven German sites at approximately 9°E, with latitudes ranging from 54.3°N (*top*) to 48°N (*bottom*). The irradiance values are ranging from 0 to 900 W/m^2

One day of instantaneous values (minutes) of global horizontal irradiance measured at Oldenburg, Germany, 1993 (*solid line*). The *dashed lines* are empirical values for clear and cloudy states and a threshold value to distinguish between them

different measurement phases, the station distances ranged from a few hundred meters to a few hundred kilometers. For very small separations, a network of 15 sensors at distances of 50–300 m has been installed on roofs of the Oldenburg University Campus. Data have been recorded with a time resolution of 1 s during 1 year [8].

In Japan, a lattice of nine pyranometers within an area of 4 × 4 km^2 has been installed to record 1-min GHI data [9].

Solar Radiation, Spatial and Temporal Variability. Figure 4
Presentation of the interannual variability of monthly sums of GHI for the two Italian sites Torino (45.220°N, 7.650°E) and Brindisi (40.660°N, 17.950°E) given by the annual course of multiyear averages (from a 30-year period of ground measurements [Servizio Meteorologia dell'Aeronautica Militaire, http://clima.meteoam.it/Clino61–90.php] and a 15-year period of satellite-derived data) and the annual course of maxima and minima of the monthly sums

The Israel Meteorological Service and Ben Gurion University established the Negev Radiation Survey in the 1980s collecting data of 10-min GHI and direct normal irradiance (DNI) at nine stations in Israel's Negev desert [DOI: 10.1115/1.1756138].

In the USA, several databases of this type have been established. The Southern Great Plains (SGP) site was the first field measurement site established by the Atmospheric Radiation Measurement (ARM) Program in 1992. A site map is shown on http://www.arm.gov/sites/sgp. The Oklahoma Mesonet network consists of over 100 automated observing stations located throughout the state. It provides 5- and 15-min averaged surface meteorological data in near-real time. In addition, the Kansas Mesonet provides surface meteorology and radiation data. The 60-min data are available for 16 stations in Kansas. Data of these networks can be obtained from http://www.arm.gov.

The networks described above consist of sensors giving data for discrete points in space. In principle, the time resolution of the data sampling and the total length of the recording period may be varied within a large range. This enables an almost continuous monitoring of the irradiance field in time. In contrast, the spatial characterization of the irradiance field is limited and restricted by the number of stations used. The field can only be monitored at discrete distances. This also restricts the types of methods that can be applied to analyze the data.

For solar radiation, a supplementary source of data is given by imaging techniques. The irradiance at the earth's surface is determined by the atmospheric transmission, itself a strong function of cloudiness. Thus, automatic optical observations of clouds provide a representation of the radiation conditions. Using satellites, an almost continuous spatial coverage is obtained by cloud images sampled at discrete time intervals [10]. Another source for images is available, using ground-based cameras. The latter have been used to monitor total cloud cover [11, 12] or for studies on diffuse radiation [13, 14]. In this context, the images are analyzed with respect to the distribution of the sky dome radiance or luminance [15, 16]. For the determination of cloud structures under very inhomogeneous radiation conditions, sky images have been used for cloud field analyses [8, 17].

Images of the earth, containing information on the atmospheric state, are routinely obtained by polar orbiting or geostationary satellites, the latter provide pixel sizes of $1 \times 1\ km^2$ to $2.5 \times 2.5\ km^2$, and a temporal sampling of 15–30 min. This enables to derive hourly GHI values with a high spatial resolution and geographical coverage. The following irradiance databases all use satellite cloud data as an input to radiative models.

The server Satel-Light [18] is a European database of daylight and half-hourly solar radiation. It is based on the analysis of cloud radiance derived from Meteosat images and contains 5 years of data, with 30-min irradiance values at about 250,000 sites, http://www.satellight.com.

The SoDa Intelligent System (SoDa IS) [19] performs the integration and exploitation of diverse networked information sources that are geographically dispersed. The SoDa Service accumulates solar irradiance information from all over the world. The spatial and temporal resolution of the data is determined by the remote information sources, http://www.soda-is.com.

The 1991–2005 National Solar Radiation Database (NSRDB) [20] contains hourly global, direct, and diffuse solar radiation and meteorological data for 1,454 US stations. These time series are evaluated using cloud observations from as many ground stations. The NSRDB also offers a gridded dataset that contains satellite-derived hourly solar records for 8 years (1998–2005) for the USA (except Alaska above 60° latitude), representing about 100,000 pixel locations (at a nominal $10 \times 10\ km^2$ pixel size) (http://rredc.nrel.gov/solar/old_data/nsrdb/).

The Surface meteorology and Solar Energy (SSE) dataset (http://eosweb.larc.nasa.gov/sse/) contains parameters formulated for assessing and designing renewable energy systems [21]. It is capable to obtain data for locations, global/regional areas, and daily and monthly ground measurements. The SSE dataset is based on NASA satellite- and reanalysis-derived insolation and meteorological data for the 22-year period July 1983 through June 2005. Results are provided for 1° latitude by 1° longitude grid cells over the globe. Average daily and monthly measurements for 1,195 World Radiation Data Centre ground sites are also available. The Prediction of Worldwide Energy Resource (POWER) project (http://power.larc.nasa.gov/) was initiated to extend the SSE data till near-real time [21]. For this purpose, for example, FLASHFlux data are continuously included, which provide daily average solar irradiance derived from the polar orbiting satellites Terra and Aqua within 1 week of observation [22]. A comparative analysis of both, coarse SSE and finer-resolved NSRDB data, with SGP ground measurements has been performed to evaluate resolution-induced uncertainties in the assessment of the solar energy potential [23].

The DLR-ISIS [24] dataset is based on cloud data from the International Satellite Cloud Climatology Project (ISCCP) and radiative transfer calculations. It gives an overview of the available total solar irradiance worldwide for GHI and DNI. Its long temporal coverage over more than 21 years makes it possible to derive stable long-term averages, to evaluate the variability of irradiance from year to year and to study the effect of

extreme atmospheric conditions on the irradiance at the surface, for example, after a volcanic eruption. The temporal resolution of ISIS is 3 h, and its spatial resolution is $280 \times 280\,km^2$ (http://www.pa.op.dlr.de/ISIS/).

Apart from these satellite-based methods, the database Meteonorm [25] is a software-based collection of ground-measured monthly averages of GHI and temperature. It contains 2,400 stations with at least 10 years of data. The user is proposed interpolated monthly data for intermediate sites as well as synthesized hourly values. For the generation of these values the inclusion of the spatial and temporal variability of the irradiance field is required. The user gets site-specific data containing the temporal variability. Nevertheless, this dataset is not usable for statistical correlation analysis, since all short-term data are synthetic.

Finally, the European Solar Radiation Atlas (ESRA) [26] contains digital maps of monthly averages of direct, global, and diffuse radiation at a resolution of approximately $10 \times 10\,km^2$. These maps result from the merging of ground-measured radiation data and coarse resolution satellite-based irradiance maps [27]. Measurements of daily sums of irradiance at 90 sites and of hourly averages at six sites are additionally included.

Temporal Variability

Different authors investigated the variability of solar radiation time series with traditional statistical characterization tools. As a measure of temporal variability, it is common practice to calculate the mean and standard deviation of the time series. Moreover, efforts have been made to characterize the distribution functions of the irradiance data and to study the sequential characteristics of the time series.

In some cases, knowledge of the statistical characteristics allows a direct evaluation of the performance of solar energy systems without a detailed hourly simulation. In other cases, for example, for systems including storage, an explicit time-step simulation is needed. For these systems, the statistical characteristics can be used to generate synthetic solar radiation time series as input for time-step simulations. Starting with a monthly average of GHI – as taken from an atlas, for instance – it is possible to generate consecutive synthetic time series of daily sums, hourly averages, and minute-by-minute values. Hopefully, such time series should carry the natural statistical characteristics by reproducing the distribution functions and sequential patterns found in measured datasets. Procedures of this kind are executed by the Meteonorm tools and within specialized photovoltaic (PV) simulation software.

If solar radiation at the Earth's surface showed strong annual variations, this could seriously harm the return of investment for solar energy projects. While long-term radiation trends are handled in detail in a different entry of this encyclopedia, brief information about their annual variations is given here in a later section about large-scale and long-term variability from satellite images.

Distribution Function of Solar Radiation

The analysis of the distribution function focuses on the identification of analytical models with a reasonable representation but only a limited number of free parameters to characterize a given situation. Authors detected different types of probability functions when observing daily values, hourly values, or instantaneous data. A summary of their findings is given in the following sections.

Probability Function of Daily Mean Irradiance

For daily mean values of irradiance, a commonly used procedure is to calculate the overall atmospheric transmission represented by the clearness index, K_t. It is defined as the ratio of the irradiance on a horizontal plane on the earth surface divided by the respective irradiance just outside of the atmosphere [28]. Ideally, K_t time series should be free from deterministic trends. However, due to systematic seasonal variations of the climatic conditions see (Fig. 5) and the dependence of K_t on the sun's zenith angle, the clearness index does not qualify as a stationary process for long time series. Shorter sections, such as monthly datasets, can approximate stationary processes.

The first distribution function of daily K_t was presented in the seminal contribution of Liu and Jordan [28]. They stated that the distribution function is mainly determined by the monthly mean value of K_t. Starting from this assumption, several models for the monthly distribution functions of daily K_t have been developed [29–32] to represent various climatic conditions, including the Tropics, and medium to high

Solar Radiation, Spatial and Temporal Variability. Figure 5
Annual course of the mean monthly clearness index (average value of 10 years) for three North German stations

latitudes. Noticing that for fixed mean values of daily K_t the standard deviation varies with location, a model for the probability density function was introduced to provide both the required mean value and variance [33].

Probability Distribution of Hourly Clearness Index Values

To properly model the distribution of hourly irradiance data as a function of the daily clearness index, it has to be considered that a daily trend of the hourly clearness index remains, which is caused by different optical paths through the atmosphere. Such models are given in [34, 35]. As an alternative, a model for the irradiance under clear-sky conditions may be used to analyze the clear-sky index K^*, defined by the ratio of the actual irradiance to the irradiance expected under clear-sky conditions. In particular, this approach has been used for the analysis of instantaneous irradiance data, as discussed below.

Instantaneous Clearness Index, Clear-Sky Index Values, and Irradiance Distributions

Data with higher time resolution have been dealt with in various studies [36–38]. They found that the probability densities of 1-min clearness index values tend to show a distinct bimodal shape. This is explained by the fact that short-term data are dominated by either one of two opposite sky conditions – *clear sky* and *cloud shadow* – whereas in hourly time series these two states are mixed by the averaging. As a model for the distribution function of 1-min clear-sky index (K^*) data, the use of two beta functions was proposed [39]. This type of model has been implemented in procedures to generate synthetic time series, which are usually applied in solar system simulation studies [40].

The variability of irradiance within an hour is important for the correct inverter sizing in PV systems, for instance. In most cases, this design is done assuming a clear-sky situation and using hourly averages of irradiance data. These hourly averages smooth out extreme values, which may, due to scattering at complex cloud structures, even be higher than the irradiance expected for a clear-sky situation. If these higher instantaneous irradiance values are neglected, an undersizing of system components as the inverter will occur. This in turn causes a loss in the system's energy output [41, 42].

The variability of irradiance within an hour can be advantageously accounted for when modeling the

diffuse fraction of hourly GHI [43]. A high variability is an indicator for sunny intervals in alteration with the occurrence of thick clouds. The diffuse fraction for a given value of GHI is in this case expected to be higher than in a clear situation with low variability. Nevertheless, for time series of hourly GHI the variability within the hour is not known, but can be estimated from the variability from hour to hour [43].

Solar Radiation Time Series Characteristics

The irradiance incident on a solar system shows variations with respect to time and location. The temporal and regional patterns are controlled by temporal and spatial correlation structures.

For the analysis of time series characteristics in solar radiation datasets, the quasi-deterministic trend function must be separated from the stochastic fluctuations. When this is done, it becomes possible to represent the stochastic part of the time evolution by a simple model process.

To model the temporal evolution of solar radiation data, autoregressive processes or Markov chain approaches have been proposed. Stochastic processes for daily and hourly data are, in general, analyzed separately. The key of the process identification is the analysis of the autocorrelation function of the residual trend-free data, for example, K_t. It is stated by several authors [33, 44–48] that the autocorrelation function of the daily radiation within 1 month can be well approximated by an exponential function see (Fig. 6). This leads to the conclusion that a model process that is discrete in time may be represented by a first-order autoregressive process or Markov chain. Examples for the application of Markov chain models for daily clearness index are given in [48, 49]. For the time evolution of hourly data within 1 day, see [34, 35].

Short-term DNI data are governed by an on/off pattern due to their distinct sensitivity to obstruction of the sun by clouds. This leads to a characterization of the temporal evolution by the respective durations of clear and cloudy periods. Probability distributions of these duration times have been presented [36, 50].

An analysis of irradiance fluctuations that focuses on their amplitude, persistence, and frequency of occurrence can be performed by a localized spectral analysis. As an outcome of such an analysis, a fluctuation power index and a fluctuation energy index have been introduced [51].

Spatial Variability

Sufficient knowledge of the spatial variability of solar radiation can help to evaluate the ideal spacing of

Solar Radiation, Spatial and Temporal Variability. Figure 6
Autocorrelation functions for time series of daily clearness index values. The curves are gained from monthly datasets from three North German stations with average clearness index value lower than 0.37. The *red line* refers to an exponential autocorrelation characteristic

measurement stations in a network. Measurements from each station shall be representative of a large area. In this kind of application, it is possible to benefit from the fact that observations at different sites are not independent, but rather that nearby sites share more similarities than sites that are far apart.

A common method to evaluate spatial variability from a set of measurement sites is the cross-correlation analysis. More details are given in the following section.

For the spatial interpolation of solar radiation data between measurement sites, advanced methods have been developed which include a representation of the spatial correlation. Other methods combine measurements with satellite data, see below.

Satellite-derived irradiance values are widely used in solar energy applications. Nevertheless, these data show a typical relative bias for GHI in the range of ±5 to ±10% and a relative rmse between 15% and 30% [52], which will affect site audit and yield prognosis. Here the question arises, whether it is better to rely on experimental measurements from a station located at y km from the site under scrutiny or on data derived from a satellite pixel containing that site [53].

Moreover, the spatial variability of irradiance causes fluctuations in the power output of large PV arrays, and may possibly affect electricity production negatively due to load imbalances. This typically occurs when a part of a large array is in the sun while another is in the shade, and is discussed in the section about small-scale variability.

Cross-correlation Analysis

The correlation of time series measured at two different sites is often calculated to analyze spatial variability. This cross correlation is expected to decrease when the distance between the sites increases. In addition, the correlation between station pairs increases with increasing averaging times.

With the knowledge of the cross-correlation structure of a set of single-point radiation time series, some global characteristics of these time series defined by their ensemble average can be described. Regarding the analysis of large renewable energy systems, this is helpful to describe the smoothing of relative fluctuations in the lumped power output of a number of spatially dispersed collectors, compared to those for a single collector [54].

It has been found [7] that the correlation of hourly residuals of German irradiance data would obey a simple exponential decay of the form $r = e^{-ad}$, where d is the distance between stations (km). A decay constant of $a = 3.38\ \mathrm{km}^{-1}$ was reported in that study. Therefore, for those conditions, the correlation coefficient drops from $r \approx 0.845$ at a distance of 50 km to $r \approx 0.5$ at approximately 200 km, and $r \approx 0.09$ at a distance of 700 km. It is generally accepted that at a distance of more than 50 km from a measurement station, it is better to use local satellite-based modelled irradiance estimates than to extrapolate those measurements. This critical distance may vary significantly as a function of terrain homogeneity, however.

Using radiation data from a network in Pennsylvania, the expected decrease in correlation with increasing distance and the increase in correlation with increasing averaging times was confirmed [4]. For daily values the correlation was found to decrease only slightly to $r = 0.97$, at a distance of 90 km. The authors found a spacing of 150 km between measurement sites reasonable to measure daily irradiance in that hilly area.

In Scotland, the time delay for maximum correlation between sites was directly coupled to their Easterly distance, between 0 and 20 km [5]. It was postulated that the correlation is a function of a combined space-time distance.

Spatial Interpolation

Spatial interpolation methods are needed to estimate solar irradiance at uninstrumented sites in a given geographic area, based on known irradiance values at some distant measurement sites. All methods estimate the unknown irradiance by a weighted sum of the irradiance measured at surrounding sites. In a commonly used approach, the weights are proportional to the inverse of the distance.

Kriging is a more sophisticated method in geostatistics. It extracts information about spatial variability from the available measurements. The spatial variability information is then used to determine the values of the weights in such a way that the error in the interpolated irradiance is minimized. For this method, the spatial correlation structure of solar irradiance is expressed by the so-called semivariogram [55, 56].

A combination of semicontinuous (gridded) satellite data with accurate local radiometric measurements can be performed by the data fusion method called Kriging of Differences. When applied to monthly irradiance values, this method was proven superior to pure satellite-derived data or to data interpolated with ordinary Kriging. The data fusion method has been selected to perform spatial interpolation for the European Solar Radiation Atlas [27], and to derive highly accurate daily irradiances for the remote monitoring of PV systems [57].

Small-Scale Variability

The passage of a field of opaque clouds may lead to large changes in the incoming irradiance when compared to the corresponding clear-sky value, for example, up to ~80% for GHI or 100% for DNI. The dynamics of the irradiance field can be assumed to be caused by wind-induced movements of such a cloud field.

Simple cloud field models have been introduced using ideal rectangular clouds [58] or ensembles of circular clouds [59].

An analysis of more realistic irregular cloud patterns resulted in a general model for the synthesis of radiation fields and their temporal evolution [8]. For this analysis, cloud field structures were extracted from sky photographs and described as fractal objects. Based on this representation, synthetic cloud patterns and their induced radiation fields could be generated, as shown in Figs. 7 and 8. Such modeled radiation fields were shown to correctly reproduce the actual measurements from an array of ground sensors, with respect to the frequency of transitions between the clear and cloudy states and the duration of either state. This method would also be applicable to obtain the probability that two measurement sites are in the same state or in opposite states. Artificial time series, as well as measured time series, show a dampening effect of fluctuations when ensemble averages are considered.

Solar Radiation, Spatial and Temporal Variability. Figure 7
A synthetic cloud shadow pattern generated by a fractal model. It is used for the generation of irradiance datasets with high spatial and temporal resolution. The cloud band covers an area of 14 × 3.5 km^2. With the assumption of a cloud drift speed of 15 m/s the clouds need 16 min to pass over this area

A similar synthesis approach was proposed [7] to expand observations of the binary cloud/no-cloud state from at least a pair of points to a synthetic cloud field. Based on the hypothesis of a rigid cloud pattern and knowledge of the drift speed, the temporal correlation structure of the cloud field is transformed into a spatial correlation structure, representing the probability of co-occurrence of clouds at points with a given spatial separation. Based on this information, a shifting cloud field showing a realistic correlation structure over space and time can be expanded from the measured radiation time series.

The dampening effect of fluctuations created by ensemble averages has been confirmed in this case by a frequency analysis of irradiance fluctuations as measured at nine sites within an area of 4 × 4 km^2 [60].

Large-Scale and Long-Term Variability from Satellite Observations

For the integration of a high share of renewable energy on a nationwide or European scale, the interaction of the renewable production with the conventional power park has to be considered. As it is necessary to balance local deficits and surpluses of supply and demand, the scheduling of the conventional power plants must be adapted and the transport capacity of the network must be sufficient. Analyses of this type that take the structure of the irradiance field explicitly into account have been performed with satellite-derived hourly maps of the irradiance field [61], giving an insight into the balancing energy flows. In this case, the structure of the irradiance field was analyzed with the help of a multi-resolution analysis of clearness index images [62].

PV electricity yield prediction should reflect the energy gain accumulated over longer periods, for example, 20 years. Thus the variability of the irradiance sum over longer averaging periods is of interest. For Potsdam and Germany, a time series of GHI has been measured for more than 60 years. Here, the yearly sum

Solar Radiation, Spatial and Temporal Variability. Figure 8
Synthetic time series of global horizontal irradiance (30 min of 1 s data) generated with a fractal cloud model as shown in Fig. 7

of a single year can deviate by ±15% from the long-term average [63]. Moreover, a minimum of 8 years is necessary to approximate the long-term average with less than 5% deviation. As this number of recommended years may vary from region to region and may be different for DNI the interannual variability was analyzed with satellite data [64]. Here, the annual sum of DNI was derived from Meteosat data for Spain for 5 years. In Spain, the individual deviation of each year (1999–2003) from the 5-year average was 30% for sites in the Pyrenees, and 10% for other large regions. This means that for DNI it is necessary to average over far more than 5 years to derive reliable long-term averages for planning.

The topic of another study was the estimation of uncertainties in yield prediction caused by fluctuations in solar radiation [65]. For this, the interannual variability of GHI was analyzed by comparing the yearly and monthly averages to the long-term values. The results are presented as standard deviation maps for the regions around the Mediterranean and Black Seas.

A study of the spatial and temporal variability of GHI, global tilted irradiance (GTI), and DNI in the USA has been performed recently [66]. Eight years of data from the National Solar Radiation Database have been analyzed. The results are presented as maps of both the interannual and spatial variations in yearly and monthly values of DNI and GTI. Besides this, the authors observed that DNI is always more variable than global irradiance. The long-term annual average of global irradiance could be estimated within ±5% after only 1 or 2 years of local measurements, whereas a similar approximation of the long-term annual average of DNI could take 10–15 years.

The long-term variability of irradiance has also been analyzed on a global scale [24]. The study is based on 18 years of DLR-ISIS data (1984–2001). It was found that, during that period, DNI significantly increased (up to +4 W/m^2 per year) over several regions in the subtropics with the exception of Australia, where a small decrease of −1 W/m^2 per year was observed. The interannual DNI variability was found very strong, and sometimes exceeded 20% relative to the long-term average. Changes in GHI were found much smaller and less significant, with a maximum increase of 0.8 W/m^2 per year and an annual variability of less than 4%. Large volcanic eruptions were found to reduce annual averages of DNI by up to 16% and annual averages of global horizontal irradiance by less than 2.2%.

The strong variability of DNI from year to year must be accounted for in estimating the energy yield of concentrating solar power plants. To that effect,

a promising method has been proposed [67]. It consists in combining precision DNI data from a measurement campaign with long-term satellite-derived data from two different sources, each spanning over a period of at least 10 years. From these separate datasets, a quality-weighted average is calculated depending on the individual uncertainties of each of them. With the help of long-term data, the most representative climatological values are determined for the final best estimate, which is required for bankable simulations of energy yields.

Future Directions

In view of future energy supply systems that will presumably include large shares of both solar and wind energy converters, the analysis of cross-statistics of solar and wind fields is important. For the treatment of the structure of the solar irradiance field, large-scale information derived from satellite images, and large-scale meteorological modeling results have to be taken into account.

The spatial variability in solar radiation has been discussed in the context of energy generation planning and of optimal structure of the supply system. In addition to these topics, forecasts of the energy flows are necessary for the operation of any electricity network. In networks with a high share of generation from wind farms and PV systems, the stochastic nature of these energy flows dominates the uncertainties in power generation and load balance, which in turn affects the load scheduling of conventional power generating capacity. Due to the high share of wind generation in national supply grids, such as in Germany and Denmark, wind power forecasts have become an integral part of everyday operations, which involve power station dispatch and power trading. Considering the expected rapid growth of installed PV capacity, short-term forecasts of PV electrical generation will have to be added. Various schemes are considered for this task, and are already under active development.

Definition of the Subject

Based on 20 years of experience, the author will inform readers on solar-driven desalination using different types of solar systems and also different desalination systems. These simple and robust devices and the use of clean solar fuel not only conserve conventional fuels but also help to produce additional water and to reduce pollutants, thus reducing global warming.

Introduction

Renewable energy–powered desalination plants operate with either a mechanical process or a thermal distillation process. In the mechanical process (reverse osmosis and vapor compression), a distinction is made between network-bound and non-network systems (isolated systems). The electrical energy needs may be provided by wind power or solar power using a photovoltaic (PV) system. Hybrid systems are often used in order to continue operation in low wind periods or at low irradiance. Some facilities, for example, use diesel engines.

In several countries (Spain, Kuwait, Abu Dhabi, Mexico, USA) test facilities have been built with larger collector arrays for multi-stage flash (MSF) and multi-effect distillation (MED) desalination plants. The collectors act through vacuum tubes and flat plate collectors. Some plants are operated with solar ponds. MSF technology does not play a significant role in low-thermal-driven desalination plants using renewable energy because of their low daily production (e.g., a few liters per day to a few cubic meters per day).

For future large-scale solar power plants, however, these processes will useful applications. Studies show the advantages of thermal desalination processes, e.g., the MED process using mechanical energy or the coupling of reverse osmosis (RO) and mechanical vapor compression (MVC). These systems offer flexibility in operation. If electrical energy from the grid is not available, energy from a MVC or RO system can be used. By combining electricity generation and the use of power plant waste heat for desalination, an overall improvement in system efficiency can be achieved.

Such a system exists in the Plataforma Solar de Almería solar field trial in Spain. The MED test facility has a parabolic field of 2672 m^2, 14 distillation stages, a gained output ratio (GOR) value of about 9, and a maximum water production of about 72 m^3/day. Another demonstration plant based on the MED process was built in 1984 in Abu Dhabi with vacuum tubes and 18 distillation stages. The maximum daily production of drinking water was about 80 m^3/day.

A new generation of solar power plants is already under construction in Spain and the US. Solar power plants are in the design stage in Algeria, Morocco, Egypt, Libya, United Arab Emirates, South Africa, Israel, Italy, Iran, and India. Development in this area is dependent on politics, industry, and science. Germany, which is actively involved in this development, has a solar tower power plant with 1.5 MW of electrical power in Jülich, which was built for research purposes.

The coupled solar desalination plants require more or less continuous operation. New thermal desalination plants are able to utilize the available energy more effectively. The specified water production ranges from 110% to 20% of nominal water output. A priority for further research is the development of appropriate energy or heat storage, which allows for both overnight electricity and ensures continuous operation of the desalination plants.

RO desalination plants must operate continuously. Their coupling with a solar power plant provides electricity for the operation of desalination; the electricity must be available both day and night. This is a process-integrated project. Because the power plants are connected to the grid, it is possible to ensure continuous operation even without advanced storage technology.

Solar Driers

Water desalination is both costly and energy consuming. Today's desalination plants operate largely with fossil fuels. Of all the world's desalinated water today, only about 0.02% is generated from renewable sources. Rising oil and gas prices, however, will exert pressure in the future on energy-intensive processes such as desalination. Solar energy provides an interesting alternative, especially because desalination is most needed where there is enough solar energy available. Many areas in the world have water shortages and also annual solar irradiance of more than 1,500 kWh per square meter.

For these areas, which are often areas with poor infrastructure, renewable-powered desalination plants could provide an alternative market with great development opportunity. Following are several different variants of desalination with renewable energies.

Simple Greenhouse Distillery

Since the end of the last century, the simplest and most-used solar thermal desalination system is the simple solar distiller: a simple container with a black base and

glass cover that evaporates seawater by the greenhouse principle and the water condenses on the glass cover. Disadvantages of simple solar stills are their low production rates of about 2 to 5 l/m^2 per day, depending on global radiation.

A variety of studies have focused on improvements in the area of single distilleries. Here the objective is first to increase the production rate and, second, to reduce costs. For small and very small plants, it is difficult to estimate the typical cost because there are many different systems around the world.

Solar Water Stills in a Large-Format Pyramid Aqua-Aero WaterSystems (Delft, Netherlands) has developed the WaterPyramid. It is basically a simple solar still at a larger scale. It consists of a transparent film stretched in a pyramid shape. The salt water is heated in the pelvic area by the incoming solar radiation and is evaporated. The condensate is discharged at the sides and can be used with appropriate treatment for drinking. In addition, the roof of the pyramid serves as a collection area for rain water, which can also be used as drinking water. The water pyramid has a total floor area of 650 m^2 and a production of about 1 to 1.2 m^3 of drinking water per day in good light. The system is used in Africa and India.

Humid Air Distillation

Another type of thermal desalination system with a heat recovery system operates with moist air. This procedure, called multi-effect humidification, is also known as humid air distillation (HAD) and was developed by ZAE Bayern and the University of Bochum. Incoming salt water is heated in the condenser by capturing the heat of condensation of the distillate. Then the raw water is heated by solar collectors or waste heat from a heat process and further heated and fed into a vaporizer. The evaporated water is absorbed by the circulating air stream and condenses back to the salt water inlet. The distillate is collected separately and taken away. This type of system is now distributed by the Terrawater (Kiel, Germany). The company offers water systems in sizes from 1, 5, and 10 up to 50 m^3 per day in modular construction. The systems can be operated from a power station with solar process heat or waste heat.

Membrane Distillation Membrane distillation (MD) is a thermal process that has been studied by Fraunhofer Institute for Solar Energy Systems ISE (Freiburg, Germany) and TNO (Delft, Netherlands). The separation of water and salt is achieved by the evaporation of water through a microporous hydrophobic membrane (e.g., PTFE), which on one side is not wetted by the surface properties of liquid water, and on the other by side, because of its high porosity, water vapor does pass through very well. The driving force here is the temperature difference between the partial vapor pressures of the evaporator and the condenser surface on the other side. Between the two surfaces is the distillate channel, which is separated by the vapor-permeable membrane from the hot brine and a waterproof membrane from the inflowing water in the condenser. Since only vapor can penetrate the membrane, the result is pure distillate.

Solar Desalination Using Multi-stage Desalination with Heat Recovery Another type of solar still uses multi-stage desalination (MSD) with heat recovery. They work with a number of stacked shelves and use the heat of condensation of each deeper level. This is an open system, the pressure in each stage corresponding to the ambient pressure. Unlike with MSF or MED plants, this system cannot be adjusted by changing the boiling temperature of the pressure levels. The heat supply is the salt water at the lowest level at about 95–100°C and caused to evaporate. The vapor in the rising, moist air condenses on the lower side of the overlying evaporative stage. The condensation freed by the evaporation is released into the overlying stage and heats the salt water therein. The condensate runs off at the bottom of the capacitor steps and is collected and directed into a sump at the deepest point of the system. The heat inputs into the next higher level for re-evaporation and condensation. The resultant heat recovery reduces the specific heat consumption per liter of distillate.

The maximum size of the plant is estimated at about 5–10 m^3/day. The systems can also operate with vacuum tubes or flat plate collectors. No external electrical power is required to operate the plants. The systems regulate themselves and require very little maintenance. The plants can be operated, for example, with waste heat from diesel engines. This is increased by

the continuous operation of desalination plants on the daily output by about a factor of 3. The Solar Institute Jülich and the engineering firm IBEU (Jülich, Germany) have developed and tested this system.

Reverse Osmosis with Photovoltaic Reverse osmosis (RO) and multi-effect desalination with mechanical vapor compression (MED TVC) are mechanically driven processes. Solar-powered reverse osmosis is, in remote areas, an attractive alternative because it can be used on proven components and consumes little power. This system represents about 60% of the total drinking water that is produced worldwide with renewable energy sources. Solar-thermal-powered MSF or MED account for 25%. The cost for water systems with a daily capacity of 12–120 m^3 per day is at 3.5–20 €/m^3. However, this system requires the chemicals for water treatment, replacement of membranes, and trained users. Furthermore, larger RO plants must be uniformly supplied with energy, because they can suffer substantial damage to the operation of the fluctuating energy. When operating with unpredictable energy sources such as solar and wind power, it is necessary to have uninterrupted energy, e.g., with storage, which increases the cost of the system.

Thermodynamic and Electrical Characteristics Thermal desalination is energy intensive. The evaporation of 1 kg of water requires 0.645 kWh of energy. Therefore, all major systems work with heat recovery. Efficiency increases with a heat recovery system compared with a simple solar still without heat recovery.

To compare solar-thermal with mechanical desalination plants, there are several specific characteristics to be assessed. A measure of the degree of heat recovery is the GOR value, the utilization of energy provided for the process. It is advantageous to consider the GOR value for the desalination system and for the overall system (with collector field). Other important benchmarks are the specific daily amount of drinking water produced in kilograms per m^2 collector area and the specific electrical energy consumption (ECsp) counted in kWh per m^3 drinking water. It should be noted that, in thermal systems, the drive is electrical energy (pumps etc.), e.g., energy related to PV generation must be taken into account.

$$GOR = \frac{m_{DES}{}^{*}\Delta h}{Q_{Solar}{}^{*}A_{Koll}}$$

$$GOR = \frac{m_{DES}{}^{*}\Delta h}{Q_{Solar}{}^{*}A_{Koll} + E_{PV}/\eta_{Pv}}$$

$$m_{sp} = \frac{m_{Des}}{A_{Koll} + A_{PV}}$$

$$EB_{sp} = \frac{E_{Strom}}{\dot{V}_{Des}}$$

= temporal distillate quantity in kg/h
m_{DES} = distillate=weight in kg/day
= temporal distillate quantity in kg/h
(t) = global radiation in W/m
EB_{sp} = specific energy consumption in kWh/m^3
E_{PV} = electrical energy consumption of the system in kWh/day
E_{Strom} = current consumed amount of investment in kWh/day
Δh evaporation = 0.645 kWh/kg
Q_{Solar} = total solar radiation on the collector surface in kWh/m^2 d
A_{Koll} = total collector area in m^2
A_{PV} = PV area in m^2
η_{Pv} = chain efficiency of the PV system as a whole
$\dot{m}_{Des}(t)$ = Temporal distillate quantity in kg/h
m_{Des} = temporal distillate quantity in kg/h
$\dot{V}_{Des}$ = temporal distillate volume in m^3/day
$\dot{E}(t)$ = global radiation in W/m^2
EB_{sp} = specific energy consumption in kWh/m^3
E_{PV} = electrical energy consumption of the system in kWh/day
E_{Str} = consumed electrical energy in the System in kWh/day
Δh = evaporation enthalpy 0.645 kWh/kg
Q_{Solar} = total solar radiation on the collector surface in kWh/m^2d
A_{Koll} = total collector area in m^2
A_{PV} = PV area in m^2
η_{PV} = Overall efficiency of the PV system

Comparison with Renewable Energy Powered Desalination Table 1 provides information such as specific energy consumption in kWh/m^3 of drinking

water, the approximate production costs in €/m^3, and the state of technological development of different plant types. In the water development costs, the cost of building infrastructure is not included. These costs vary depending on location; for small water systems, the development costs more than double. Note also that many plants are not yet in the mature stage of development and, therefore, the specific values are approximate and objective.

Small Rural Infrastructure Facilities for Poor Regions For small systems there is a high demand, especially in arid zones of structurally weakness in developing and emerging countries, but most users do not have the money to finance such plants. For the distribution of these small plants there is a big need for national or international financial support. This requirement is not limited to the desalination of brackish water and seawater, but also in regions with naturally contaminated groundwater. Particularly noteworthy are boron, arsenic, fluoride, and lead, which occur often in such high concentrations that drinking this water is very harmful.

Solar Thermal Desalination Markets

There is currently no functioning market for small solar-thermal desalination. Previous installations of various small plant types were usually subsidized research and development projects. However, interest has increased in large solar-thermal power plants combined with big desalination units that co-generate of water and electricity. In markets with a high demand for drinking water, desalination systems that use waste heat from the power plant process are cost-effective. Studies of the DLR (German Aerospace Agency) show that it is advantageous to combine, for example, thermal desalination processes such as MED with

mechanical processes such as RO or MVC. This variability optimizes the operation of all units in use. Electrical energy from the grid can ensure the continuous operation of MVC or RO systems.

Solar Thermal Energy, Introduction

Christoph Richter
Project Manager Solar Research,
Plataforma Solar de Almeria , Institute of Solar Research, DLR – German Aerospace Centre, Germany

Contrary to a common saying, rather than money it's the sun that moves our world, makes it "go round." The tiny portion of the energy, this huge fusion reactor emits continuously that reaches the earth in 1 year is about 10,000 times more than the energy consumption of mankind during the same time. Absorbed in the atmosphere and on the earth surface itself, it provides the temperature range enabling our ecosystems to exist and is also responsible for a large part of our available renewable (wind, waves, biomass) and fossil energy sources.

This section deals with technologies that actively convert solar radiation into useful heat, in a temperature range from little above ambient up to more than 1,000°C, covering a broad range of energy services such as space heating, cooking, domestic hot water supply,

Solar Thermal Energy, Introduction. Figure 1
Early attempts of solar thermal energy applications. (Ref. [1])

electrical power generation, and high temperature thermochemical processes.

The history of ideas and devices to use solar thermal energy is very long. Archimedes is said to have defeated the Roman fleet attacking Syracus 300 B.C. by concentrating solar radiation with mirrors on the wooden ships to set them on fire. Though this is certainly not true as depicted, it illustrates an early understanding of the important principle of applying solar thermal energy, the concentration of light to achieve higher temperatures and therefore more application possibilities. In the late nineteenth century, A. Mouchot, a French engineer, developed several prototypes of solar engines, using concentrated solar light to operate a steam engine. Similarly, in 1912, the American engineer, F. Shuman constructed in Egypt a first parabolic trough collector (see Fig. 1, left) to drive a steam engine for water-pumping purposes. The major developments however that lead to the currently available technologies for solar thermal energy applications have been initiated mainly after the first oil crisis in 1973.

Section Content Overview

Solar thermal energy use can be classified in one way by the temperature range achieved and the corresponding applications. It is widely used already for heating purposes (water, space) in the "low" temperature range up to about 100°C, using mainly nonconcentrating collectors, higher temperatures can be achieved with more sophisticated solar collector technologies and over 200°C require concentrating solar radiation through typically mirror systems. The different technologies are described in detail in the following entries of this entry. The entry "► Solar Collectors, Non-concentrating" gives an overview of solar collector systems in the lower temperature range. Another traditional application the direct use of solar radiation for food processing, namely cooking and drying is resumed in the entry "► Solar Cookers and Dryers to Conserve Human and Planet Health." Solar energy can also be applied for cooling purposes, which can offer the advantage of a good overlap of resource (solar radiation) and demand (cooling). This is described in detail in the entry "► Solar Cooling Systems."

Another group of sections deals with technologies that have as a primary application focus the production of electricity through conversion of solar radiation first to heat, driving a mechanical conversion system coupled to an electric generator. This approach offers the intrinsic option for intermediate and cost-effective storage of the heat generated in the first step and therefore decoupling electricity production from solar radiation availability. The entry dealing with different systems for concentrating solar energy for conversion to electricity are "► Parabolic Trough Solar Technology," "► Linear Fresnel Collectors," and "► Concentrating Receiver Systems (Solar Power Tower)." Nevertheless, the high temperature heat generated in

these systems can also be applied to industrial process heat applications of all kind. The entry on "► Solar Updraft Towers" describes another approach to generate electricity using the primarily production of warm air to drive a wind turbine in a very high tower for electricity production.

The intermittent character of solar radiation makes storage systems highly desirable to match demand and thereby increase the range of application of solar energy. Technologies for this purpose are described in the respective entry "► Thermal Energy Storage." One important potential application of solar thermal energy is desalination, last not least because of the typical overlap of regions with high insolation and low water availability. This is the topic of the entry "► Solar Thermal Desalination."

The Solar Radiation can also be applied to drive chemical processes. One branch of applications in the future can be high temperature thermochemical processes to produce, for example, hydrogen or other chemical commodities for either energy or material applications. Solar Furnaces are one tool to develop such applications. The entry "► Solar Energy in Thermochemical Processing" deals with these applications. Detoxification of contaminated waters is an interesting application that has received much attention by researchers during the last decades to tackle the growing water problems. Technically, it does not rely primarily on thermal processes but direct photochemical processes induced by sunlight. It is described in detail in the entry "► Solar Detoxification and Disinfection of Water." In this area, different demonstration plants have been recently developed. An industrial plant with 100 m^2 of CPC collector surface (for photo-Fenton oxidation), combined with a biological treatment plant based on an immobilized biomass activated sludge reactor (1 m^3 of total volume) was designed and constructed for the treatment of 4 m^3/day of saline industrial wastewater containing around 600 mg/L of a nonbiodegradable compounds and from 400 to 600 mg/L of dissolved organic carbon [2]. The technical feasibility of a large-scale combined solar photocatalysis/aerobic biological process for the treatment of wastewater polluted with pesticides has recently been evaluated. Partial photo- oxidation was carried out under sunlight in a 150 m^2 CPC-based plant. Afterward, complete wastewater treatment was performed in a biological system based on immobilized biomass reactors filled with Pall®Ring supports colonized by activated sludge from the municipal WWTP [4].

Overall, the perspectives for the future contribution of solar energy to the global energy mix are very high, as one example the possible development of solar electricity from solar thermal power plants according to the roadmap of the International Energy Agency is shown in Fig. 2, with about 11% of contribution to electricity supply.

Greenhouse Large translucent solar collector roof under which air is heated by solar radiation.

Solar updraft tower (SUT) Solar Power Plant where ambient air is heated in a greenhouse and rises in a centrally installed tower tube. This convective flow drives one or more turbines to generate electricity.

Solar energy utilization Conversion of the electromagnetic radiation from the sun into usable energy, mostly heat, electricity, or chemically stored energy.

Levelized electricity cost (LEC) LEC is an economic assessment of the cost of an energy-generating system including all the costs over its lifetime: initial investment, operations and maintenance, cost of fuel, and cost of capital. The LEC is the minimum price at which energy must be sold for an energy project to break even.

Definition of the Subject and Its Importance

Electricity generation based on renewable energy is of utmost importance to replace power generation using fossil fuels, as the latter is damaging the environment and exhaustible [1, 2]. Solar energy as a resource is abundant. Several technological options exist to utilize solar radiation. Solar Updraft Towers (SUTs) are one of them. They work on a simple well-known principle: Hot air rises. To make use of this simple physical fact for power generation, air is heated by the sun under a large translucent roof (greenhouse effect). The heated air is then sucked in by a central vertical cylindrical tube (chimney effect). The updraft wind, thus created, drives turbines with generators and so generates electricity. The principle has been proven by building and successfully operating a prototype in Spain for 7 years.

Introduction

Current electricity production from coal, oil, and natural gas is damaging the environment; it is nonsustainable, and many developing countries cannot afford these energy sources. Nuclear power stations are an unacceptable risk in most locations. But inadequate energy supply leads to or maintains poverty, which commonly is accompanied by population explosion: a vicious circle.

Sensible technology for the wide use of renewable energy must be simple and reliable, accessible to the technologically less developed countries that are sunny and often have limited raw material resources; it should not need cooling water or produce waste and should be based on environmentally sound production from renewable or recyclable materials.

The solar updraft tower meets these conditions and makes it possible to take the crucial step toward a global solar energy economy. Economic appraisals based on experience and knowledge already gathered have shown that large-scale solar updraft towers ($\geq$100 MW) are capable of generating energy at costs close to those of conventional power plants [3, 4]. This is reason enough to further develop this form of solar energy utilization, up to large, economically viable

units. In a future energy economy, solar updraft towers could thus help assure the economic and environmentally benign provision of energy in sunny regions.

Although invented by others already 100 years ago [5], it was the German engineering office Schlaich Bergermann und Partner that has taken up the solar updraft tower concept about 30 years back and developed it to the present stage of technical and economical feasibility [3, 6–12]. Thermodynamic behavior has been investigated and tested in a pilot plant in Manzanares in Spain, forming the basis for the layout of large plants. (In 1903, Spanish Army Colonel Isidoro Cabanyes first proposed a solar chimney power plant in the magazine *La energía eléctrica*. One of the earliest descriptions of a solar chimney power plant was written in 1931 by a German author, Hanns Günther. He already described the Desertec concept [see http://www.desertec.org] too.)

Extensive research work and detailed analyses have proven the constructibility of huge towers in general and have resulted in an economically optimized structural concept for tower and collector [9].

Solar Updraft Tower Technical Concept

Principle

Man learned to make active use of solar energy at a very early stage: Greenhouses helped to grow food, chimney suction ventilated and cooled buildings, and windmills ground corn and pumped water.

The solar updraft tower's three essential elements – solar air collector, chimney/tower, and wind turbines – have thus been familiar for centuries, but are combined now in a novel way.

The principle is shown in Fig. 1: Air is heated by solar radiation under a low circular transparent roof open at the periphery; the roof and the natural ground below form an air collector. In the middle of the roof, there is a vertical tower with large air inlets at its base. The joint between the roof and the tower base is airtight. As hot air is lighter than cold air, it rises up the tower. Suction from the tower then draws in more hot air from the collector, and cold air comes in from the outer perimeter.

Thus, solar radiation causes a constant updraft in the tower. The energy contained in the updraft is converted into mechanical energy by pressure-staged turbines at the base of the tower and into electrical energy by conventional generators.

Solar Updraft Towers. Figure 1
Solar updraft tower principle

Solar Updraft Towers. Figure 2
Electricity generation of a solar updraft tower is in proportion to the volume defined by tower height and collector diameter

Continuous 24-h operation can be achieved by placing tight water-filled tubes or bags under the roof (Figs. 9 and 10). The water heats up during daytime and releases its heat at night. These tubes are filled only once; no further water is needed.

Electrical output of a solar updraft tower is proportional to the volume included within the tower height and collector area (Fig. 2). The same output may result from a larger tower with a smaller collector area and vice versa.

Components

The main SUT components are collector with (natural and optionally additional) storage, tower tube, and turbine(s). They are described in this section.

Collector The air in a solar chimney is heated by making use of the greenhouse effect in a simple air collector consisting of a glass or plastic roof (either sheet plastic or plastic membrane) a few meters above the ground and the ground beneath it. Only near the chimney's base does the roof rise to 20 or 25 m in order to keep the air velocity within reasonable bounds and thereby reduce friction losses, afterward at the center redirecting the air upward. This roof allows the short-wave solar radiation to penetrate and retains long-wave reradiation from the heated ground. Thus, the ground under the roof is heated and releases its heat to the air flowing radially across it from the edge to the center of the collector.

The natural heat storage capacity of the ground can be enhanced by laying out tubes or casks filled with water [4, 13]. This evens out daily variations in power output up to continuous 24-h operation and complete independence of energy yield from actual insolation.

As will be later described in the section on SUT physics, air mass flow is controlled by the turbines. If the pressure differential at the turbine increases, the flow rate is reduced, and the temperature inside the collector increases. This results in an increase in collector roof surface temperature and thus an increase in thermal losses (infrared emission and convection). Thus, the pressure intake and temperature determine plant output in varying degrees. The insolation incident on the collector roof is partly transformed into usable energy by heating the air and, if additional thermal storage is installed, the water under it. The balance is lost due to reflection, convection, and emission losses as well as heat lost in the ground.

Several alternative designs have been developed for different situations. The decisive selection criteria are the delivery, manufacturing, and assembly costs at the location in relation to the expected service life and amortization period for the roof. Service life for especially durable plastic sheet and membrane roofs is roughly 15–25 years and practically endless for a glass roof. Another solution is to combine several options. Because of the temperature increase under the roof toward the chimney, a sheet-plastic roof with its higher heat transfer rate on the edge of the roof in combination with a glass roof toward the tower, perhaps with partial double glazing, might be ideal.

Glass Roof *Glass Sheet Dimensions*: Normal plate or float glass can be produced to a thickness of between 2 and 12 mm. In the test installation at Manzanares, 4 m × 1 m sections have proven themselves for years (Fig. 3). Comparative tests have shown that a 4-mm thickness can be regarded as ideal for 1–1.2-m sections.

Three millimeters would be sufficient for 1–1.2-m widths with heat-strengthened glass, and 4 mm could be used for 1.5–1.65-m panes. The final selection depends on cost.

Coated Glass: Low-E glass, i.e., glass with a low coefficient of emission in the infrared range, can be used to improve collector efficiency, reducing heat loss to between 1/4 and 1/5. The cost of coating the glass may be compensated for by improved efficiency. From a structural design point of view, it is no different from uncoated regular glass.

Double Glazing: Double glazing or insulating glass with sealed facet joints can be used to reduce heat loss; however, the higher cost is very likely not compensated for by heat savings achieved. Furthermore, support structure loads are greater, and work-intensive sealing of the glass joints is also costly.

Solar Updraft Towers. Figure 3
Manzanares prototype glass roof

Therefore, coating and double glazing are, at most, options for the area around the chimney where air temperatures increase significantly.

Acrylic Glass: If a net savings is involved, transparent plastic panels, e.g., PMMA or polycarbonates, may be used instead of glass.

Glass Roof on Hanging Steel Bands: Slightly sagging steel bands at 1–1.2-m intervals between thin tube supports in concrete bore-pile foundations (depending on construction site) with lightweight 9/9-m^2-grid trussed support girders in one direction at right angles to them, support the glass panes attached to them (Figs. 3 and 4). Total roof area should therefore be divided into 90/90–135/135-m^2 segments. The upper rail of the support girders could be used for "vacuum cleaner" tracks.

This design was proven in Manzanares for many years with no damage even during heavy storms.

The wind wake behind the tower can negate the weight of the light support construction so that it curves upward (as it did in Manzanares without being damaged in the process). Especially where wages are high and steel cost is relatively low, the right solution might be to use bending supports in both directions. The amount of steel required is minimal, with a 6.0/4.8-m^2 support grid. Rolled beams (again with rails) cross the 6 m, and folded sheet-metal support purlins are placed at right angles to them every 1.8 m. This roof is completely level (Fig. 5). As an alternative, it can be finished with plastic panels instead of glass.

Sheet-Plastic Roof: Sheet plastics have a shorter service life than glass, but today, they are very resilient and transparent while they are not only cheaper to produce but also surprisingly advanced with regard to energy consumption.

For producing 1 m^2 of 0.2-mm-thick HP-PE plastic sheet, ~4.4 kWh per square meter of sheet plastic are required, whereas for 1 m^2 of 4-mm-thick glass, ~38 kWh per square meter of glass are required, almost nine times as much energy. However, in the future, the energy source for making the glass could be the inexhaustible sun, whereas oil is always required for plastic (with 1 l oil ≅ 10 kWh).

Plastic Sheet Funnel Roof: This option with several plastic sheets, which were not yet very resilient at the time, was tested in Manzanares (Fig. 6). Clip profiles were arranged in a 6/4-m^2 support grid onto which plastic sheets, heat-sealed – not cut – from parallel strips, were clipped. A hole with a perforated plastic disk was placed in the center of each square for draining rain water, and the sheet was anchored to a foundation in the ground, stretching it into a funnel. Because of the central anchoring foundations which have to absorb the entire wind wake, this design can only be efficient under very favorable site conditions. On the other hand, this roof can be set up by untrained labor without problem.

Plastic Sheet Roof on Arches: For long service life without wrinkles and local tears, the sheets should, if possible, curve evenly and be continuously clipped onto the edges. With a low-cost commercial thin polyethylene sheet (coated on both sides), sufficient weft, warp, and seam strengths can be achieved. In this option, arches typically form a 4/10-m^2 grid with

Solar Updraft Towers. Figure 4
Schematic of glass roof on purlins (bending supports)

Solar Updraft Towers. Figure 5
Schematic of collector roof with purlins

Solar Updraft Towers. Figure 6
Manzanares prototype plastic sheet roof

Solar Updraft Towers. Figure 7
Drawing of saddle-shaped plastic sheet roof

10-m tie rods every 4 m and simple supports placed at right angles to them (which also support the vacuum cleaner). Plastic sheets of 10 × 40-m^2 are then spread over them like a saddle (Fig. 7).

Designing the Canopy near the Tower There are high wind wake loads near the tower, and the air temperature under the roof increases so steeply that in the region closer to the tower stronger (toughened)

and/or thicker glass or double glazing must be used. Very close to the tower, in the area where also the turbines are, a solid trapeze sheet-metal roof should be considered.

Vacuum-Cleaning the Roof In the Manzanares experiment, the collector roof could safely be relied upon to be cleaned by occasional rain showers; however, this depends on the site. Of course, pure sand deserts are unsuitable (not only) because of the infrequency of rain on one hand and sandstorms resulting in grit and sand deposits on the other. In some cases, operators will have to provide some active cleaning. Especially designed vacuum cleaners are a useful, simple, and affordable solution for this purpose. They can ride on tracks that are an integral part of the roof supports (Fig. 8).

The amount of sand to be cleaned away and the power requirements for the fan and the drive are now estimated. Three alternatives are compared below for the vacuum cleaner power supply: photovoltaics, motor-driven winch, and engine.

The simplest solution would be the engine. Guiding a winch cable is complicated. Photovoltaics is simple and reliable in keeping with the plant's technology, but as the batteries are too heavy and expensive, such cleaners can currently only be used for about 10 h at a time.

Sand containers at the end of every lane must be emptied, and the cleaner has to move up or down the track. The transfer position is recognized by sensors, a second set of wheels at right angles to the first set emerges, and the cleaner goes over onto the next track up or down on transfer tracks.

Storage If additional thermal storage capacity is desired, water-filled black tubes or other casks or containers are laid down side by side on the

Solar Updraft Towers. Figure 8
Vacuum cleaner (conceptual design)

radiation-absorbing soil under the collector [13]. The tubes are filled with water once and remain closed thereafter so that no evaporation can take place.

The water inside the tubes stores a part of the solar heat and releases it during the night when the air in the collector cools down. This enables the plant to run for 24 h/day on pure solar energy (Fig. 9).

The volume of water in the tubes is selected to correspond to a water layer with a depth of 5–20 cm depending on the desired power output characteristics (Fig. 10).

Heat storage with water works more efficiently than with soil alone, since even at low water velocities – from natural convection in the tubes – the heat transfer between water tubes and water is much higher than that between ground surface and the soil layers underneath, and since the heat capacity of water is about five times higher than that of soil.

Because of their strong impact on the service life of the storage system and the cost of power generation, the materials suitable for these hoses and related manufacturing and assembly techniques were

Solar Updraft Towers. Figure 9
Principle of thermal energy storage with water-filled tubes

Solar Updraft Towers. Figure 10
Effect of heat storage underneath the collector roof using water-filled black tubes

examined in detail according to a list of required properties: short- and long-term mechanical resilience, heat resistance, UV resistance, aging and long-term properties, width, joining techniques, and cost. The materials compared were glass, textile materials, plastics (PE, PP, PVC, PTFC, ETFE, polyester), and aluminum.

Glass had to be excluded for design and cost reasons. Water tightness is a problem for using aluminum, especially at the welding seams, and is not to be recommended for ecological reasons because of the high energy expense during its production.

High-performance plastic materials, such as PTFE, ETFE, and others, are not an option because of their high cost and because they are still hard to weld. Polyester, which is otherwise highly suitable, is excluded because at temperatures exceeding approximately 80°C hydrolysis tends to make the material brittle, provided this tendency cannot be eliminated. PVC is also only heat resistant up to 75°C.

Polyethylene (PE), a low-cost, worldwide available standard plastic material, available in widths of up to 11 m because it is manufactured by extrusion, seems to be suitable for the application in question, despite its sensitivity to heat and UV radiation. One factor in favor of PE is the fact that a glass collector roof absorbs much of the UV radiation. Quenchers and UV absorbers as well as heat stabilizers added to the plastic material increase durability and thus the service life of the material if it is thick enough (though unfortunately, also raising the material price). PE sheets are used in construction and for reservoirs and have a proven service life of more than 20 years.

PE is easy to weld and the seams are watertight. Cushions are spread radially on the leveled collector floor. Another factor in favor of "airbed storage" is the fact that ground leveling is hardly necessary as the water circulates in a closed circuit. The pressure created by irregularities in the ground and expansion of the water because of temperature changes has to be absorbed by the hose/cushion material.

The cushion consists of a thin plastic sheet above water level and a second one below it, the latter being thicker to provide mechanical protection against irregularities on the ground (Fig. 11).

Solar Updraft Towers. Figure 11
Water cushions as heat storage

Tower The tower is the plant's actual thermal engine [14]. It is a pressure tube with low friction loss (like a hydropower station penstock) because of its favorably low surface–volume ratio. The updraft of the air heated in the collector is approximately proportional to the air temperature rise (ΔT) in the collector and to the height of the tower. In a large solar updraft tower, the collector raises the air temperature by about 30–35 K. This produces an updraft velocity in the tower of about 15 m/s at full load. It is thus possible to enter into an operating solar tower power plant for maintenance without danger from high air velocities.

Loads on the Tower The main wind, seismic, and settling loads on the tower depend on the site. Added to this are site-independent differences in temperature and construction imperfections other than defects.

Wind Wind being the main load, detailed expert reports on wind conditions up to a height of 1,000 m were obtained from leading specialists in their field [15–18].

The mean wind speed curve at different heights and gust frequencies greatly depends on topography.

Potential solar tower sites are usually characterized by level surroundings having no natural obstacles. This means that during the first 100 m above ground, wind speed increases sharply, slowly becoming nearly constant after that. Above 300 m, no significant increase in wind speed need be expected.

Gusts are mainly caused by irregularities in the ground. At greater heights, the influence of the

topography, and thus frequency of gusts, drops off. This can be expressed as turbulence intensity (Fig. 12).

The development of wind speed and turbulence can be explained very well with theoretical models which have been confirmed by actual measurements. The Deaves and Harris wind development model [19] is recognized around the world. Theoretical models for the particular site can be calibrated by measuring wind speeds at a fixed reference height for several years.

How much a gust influences a building strongly depends on how large the gust is, and how fast it is moving, compared to the size of the building. The smaller a gust is, the faster it moves. A gust over 1,000 m wide will hit the whole tower, but it is only 10% faster than the mean wind speed. Smaller gusts of only 50 × 50 m can double the wind speed in the area they hit. However, their effect on the tower and its foundations will again be slight because of their limited size. Therefore, several combinations of gust patterns have to be applied to the tower during the planning stage.

The impact pushing or pulling on the surface of the cylinder can easily be determined based on gust speed. Figure 13 shows the distribution of pressure and suction on the cylinder surface and how it was determined by experiments on circular tanks.

The pulsating effect of gusts can, furthermore, cause structural oscillation. Factors increasing this dynamic load are calculated by analyzing oscillation inherent in the structure.

Apart from induced oscillation in the direction of the wind, shear vibration can be induced in towers with circular profiles because vortices are regularly shed when their inherent oscillation (eigenfrequency) f_e equals the shedding frequency in the von-Kármán vortex street (Fig. 14) $f_w = v * S/D$ (with S = 0.2 for the circular profile).

Because of its large diameter, the critical wind speed,

$$v_{krit} = f_E * D/S,$$

for the tower of a solar tower power plant is larger than the maximum wind speed attained. Therefore, shear vibration cannot be induced.

Solar Updraft Towers. Figure 12
Wind speed distribution and turbulence intensity up to a height of 1,000 m above ground (Deaves-Harris model, [19])

Solar Updraft Towers. Figure 13
Distribution of impact on the circumference of a cylinder

Earthquakes In choosing large-scale power plant sites, extreme danger of earthquake must usually be eliminated. Earthquakes accelerate a building's mass, which results in certain horizontal forces. If the maximum acceleration to be expected at a site as a result of an earthquake results in weaker horizontal forces than from wind, there is no danger to the tower because the probability of maximum wind strength and a very strong earthquake occurring at the same time is negligible.

Settlement The soil under the tower's foundation settles to a certain degree depending on the composition of the ground. Regular settlement is not critical for the layout of the tower and does not affect its operation. However, if the ground under the foundation settles irregularly, it can cause the tower to lean, resulting in additional loads. To avoid this, on less suitable construction sites, the tower foundation is built on a rigid concrete slab, or the tower can be built on piles which, if possible, reach down to a solid rock layer in the ground. Usually, however, suitable construction sites with regular settlement patterns may be expected in arid regions and deserts considered possible sites for solar updraft towers.

The foundation design depends on the site and ground conditions there. For example, soil compacting under the foundation varies greatly depending on the soil's rigidity although the weight is distributed.

Temperature The differences in temperature between inside and outside can greatly affect curved shell structures. For example, there are wide temperature differences when the sun shines on only one side of the tower in the morning when the plant is offline, resulting in relatively low air temperatures inside the tower. Other typical cases are night operation from heat storage or morning operation. The air rising in the tower can easily reach temperatures in excess of 50°C. With a morning ambient temperature of 10°C, temperature differences could exceed 40 K, often leading to cracks in the concrete surface. However, calculations have proven that this does not endanger tower stability.

Imperfections There are always small, unavoidable imperfections in construction. On a building site exposed to the elements at an altitude of over 800 m, it must be assumed that the tower is not always built perfectly vertical and that the walls will have larger or smaller dents in them. From measurements of many cooling towers, however, the usual tolerances for such

Solar Updraft Towers. Figure 14
Regular shedding of vortices on a circular cylinder (Kármán vortex street). *Top*: schematic and formula, bottom: photo from laboratory tests in water channel

imperfections are known. Special measuring programs using laser and GPS ensure that these tolerances are not exceeded even at heights of 1,000 m. In tunnel construction, perforations several kilometers long are made right on target.

The influence of unavoidable imperfections must be taken into account in the plant layout as they often have considerable impact on shell stability.

Spoked wheels (Fig. 15) are used to stiffen the thin shell wall in such a way as to prevent classic buckling.

Calculations and *Layout for 1,000-m Tubes*: The finite elements method can be used to efficiently calculate linear elasticity for the entire tower. Of course, it is not sufficient to rely on a single computer program, but results of various independently developed finite element software packages have to be compared.

Even the linear calculation clearly demonstrates the favorable effect of spoked wheels. The strong membrane forces of an unstiffened cylindrical shell are almost reduced to those of a cylindrical shaft (Fig. 16).

The suction bulge of the tube without spoked wheels – a reference for the amount of reinforcement steel required – and the pressure dent – a reference for the wall thickness required – are completely leveled out when spoked wheels are used so that construction cost can be reduced and stability increased (Fig. 17). Furthermore, the spoked wheels prevent oscillation of the entire cylinder wall over almost 1,000 m (Fig. 18). This type of oscillation could otherwise be caused by vortex shedding and quickly lead to the building's collapse because of the significant distortion. The spoked wheels completely prevent this type of oscillation. Figure 18 shows oscillation with spoked wheels on the right. No load caused by natural wind would result in such a curve. Therefore, with regular vortex shedding, there is no danger to the spoked-wheel shell.

Modern finite element software, furthermore, makes it possible to use nonlinear geometric and material calculation methods which take into account crack in the concrete surface as well as plastic deformation in the steel reinforcements. All of this makes for a very realistic representation of the tower's actual characteristics and thus provides a good understanding of its load-bearing properties, giving the impression that it is sufficiently safe (Fig. 19).

The German standard for steel-reinforced concrete construction (DIN 1045–1) stipulates a load-bearing factor of at least 1.3. The calculations carried out so far, in part at the University of Stuttgart, have shown a load-bearing factor of approximately 1.7. By taking into account the nonlinear properties of steel-reinforced concrete, the reinforcement distribution shown above can be further improved as the loads are displaced (Fig. 20).

Calculations and Layout for Base and Foundation: The lower support structure is also calculated with the finite elements method, taking the ground's rigidity into account (Fig. 21). This makes it possible to comprehensively determine the impact of settlement and the maximum soil compression. The stability of the wall sections is ensured by a geometrically nonlinear calculation method.

Tie-and-strut models are used for the highly stressed area at the transition from the circular cylinder to the wall sections on which the cylinder rests (Fig. 22). The load on the steel-reinforced concrete can be accurately calculated so that it is well within safety tolerances.

Solar Updraft Towers. Figure 15
Tower tube of a solar updraft tower power plant with spoked wheel to stiffen it

Turbines Using turbines, mechanical output in the form of rotational energy can be derived from the airflow in the tower. Turbines in a solar updraft tower do not work with staged velocity like free-running wind energy converters, but as a shrouded pressure-staged wind turbo generator, in which, similarly to a hydroelectric power station's Kaplan turbine, static pressure is converted to rotational energy [20]. The specific power output (power per area swept by the rotor) of a shrouded pressure-staged turbine in the solar updraft tower is roughly one order of magnitude higher than that of a velocity-staged wind turbine, i.e., SUT turbines are more compact as compared to wind energy converters of the same capacity. Air speed, before and after the turbine, is about the same. The output achieved is proportional to the product of volume flow per time unit and the pressure differential over the turbine. With a view to maximum energy yield, the aim of the turbine control system is to maximize this product, i.e., power output, under all operating conditions.

To this end, blade pitch is adjusted during operation to regulate power output according to the altering airspeed and airflow. If the flat sides of the blades are perpendicular to the airflow, the turbine does not turn. If the blades are parallel to the air flow and allow the air to flow through undisturbed, there is no drop in pressure at the turbine and no electricity is generated. Between these two extremes there is an optimum blade setting: The output is maximized if the pressure drop at the turbine is about 80–90% of the total pressure differential available, depending on weather and operating conditions as well as on plant design.

SUT rotors will have a larger number of comparatively thick blades (e.g., from 5 to 13 blades, compared to 2 or 3 in current wind power plants). There is a clear relationship between the solar tower turbine and the Kaplan hydroturbine, as shown in Fig. 23.

Turbine Layout Today, the state of the art places *many* small horizontal-axis turbines around the perimeter of the tower base, but for smaller plants up to a few megawatts one may install a single turbine with horizontal axis in the tower shaft.

Airflow The turbines in the solar tower are driven by the pressure difference caused by the updraft inside the tower. In order to maximize usable plant power output, it is designed in such a way as to minimize the unavoidable friction losses as air flows through the

Solar Updraft Towers. Figure 16
Sectional distribution of meridian stresses in a shaft and a shell

plant. This is achieved through the geometric design of the flow duct. The following sections aim to give an idea of the calculations and measurements required.

Calculations Flows on which the turbine layout is based are increasingly computer-calculated, and in some cases, wind tunnel experiments are conducted as well. The technical term for computerized flow calculations is Computational Fluid Dynamics (CFD). Figure 24 shows how the flow area to be investigated is divided into a mesh of numerous small control volumes for which the flow conservation equations (e.g., conservation of mass and impulse) are performed numerically by the computer. The resulting "mesh" showing the edges of the control volumes is shown.

Figure 25 shows such calculations for the flow pattern around the turbine housing graphically. Here, too, the aim is to minimize friction losses while achieving a practical shape which can be manufactured economically.

Suitable turbine blade profiles, thickness, and twist as a function of radius have to be found. The result of this process is shown in Fig. 26.

Flow Redirection into the Tower After the air has blown horizontally through the collector and possibly through the turbines (provided the turbine is not inside the tower shaft), its flow has to be redirected 90° upward into the tower shaft with minimum friction. Internal tower parts can contribute to keeping friction losses low (Fig. 27).

This also has to be ensured for asymmetrical flow patterns, e.g., if individual turbines are off-line or a part of the collector should be in shadow.

Figure 28 shows an example of the speed profiles for one option of redirectional geometry.

Solar Updraft Towers. Figure 17
Distribution of meridian forces along the wall of the tower under wind load with increasing numbers of spoked wheels

Generator The generator, which converts mechanical energy into electricity, is driven by the turbine runner. The alternating current delivered to the public distribution grid must have exactly the same frequency as the grid. Because the synchronized speed is the quotient of grid frequency and the number of pole pairs, there are certain suitable generator speed and pole pair number combinations. This is illustrated in the following example:

Grid frequency = 50 Hz (50 s^{-1})
Number of pole pairs = 2, therefore
Synchronized speed n_d = 50 $s^{-1}/2$ = 25 s^{-1} = 1500 min^{-1}

The generator in our example has to be run at exactly 1,500 rpm to generate alternating current with the required grid frequency. Alternatively, a frequency transformer can be used to match different frequencies of the SUT generator and the grid (see below).

Because of the required size (runner diameter) of the turbine and the aerodynamic requirement that the blade tips may not reach supersonic speeds during regular operation, the turbine speeds permissible in a solar tower are significantly lower than the 1,500 min^{-1} in our example. Take as an illustration a permissible 75 min^{-1} speed in a 25-m-diameter turbine. This would correspond to a blade tip speed of roughly 100 m/s. Even considering the increase in speed on the turbine blade – also at runaway speeds – the blade tip speed thus remains below the speed of sound (roughly 320 m/s at normal temperature). The following options are then still available to match the required grid frequency:

Solar Updraft Towers. Figure 18
Oscillation figures with one spoked wheel at the top (left) and with five spoked wheels

Gearing. The generator can be driven by the runner through a gear unit making it possible to adapt the speed of rotation. This solution has the advantage that cost-effective standard generators can be used. Its disadvantages are mechanical losses in the gear unit and the longer time and greater expense required for maintenance.

Larger number of pole pairs. The frequency of the alternating current generated can be increased by increasing the number of pole pairs. As pole size cannot be reduced indefinitely, this solution unfortunately requires a larger circumference and thus a greater runner diameter. Consequently, cost increases with the number of pairs of poles.

Frequency transformer. A frequency transformer inserted between the generator and the grid disconnects the two frequencies so that the turbine can also be operated at variable speed. This technology is already being used in some wind power plants where variable-frequency operation is especially advantageous.

Safety The situation becomes critical when the turbine is not slowed down by the generator, i.e., when the latter is no longer "absorbing" energy. This can happen if the generator and the grid are disconnected ("load shedding"). Without the braking effect of the generator, the speed of the turbine increases. Its acceleration is

Solar Updraft Towers. Figure 19
Shell structure load displacement properties

Solar Updraft Towers. Figure 20
Nonlinear calculation of distribution of stress from wind load

limited by the inertia of the rotating mass (meaning that the larger the rotating mass and the greater its distance from the axis of rotation, the more "leisurely" turbine speed increases). If no further precaution is taken, turbine speed increases until equilibrium is reached between the accelerating and braking forces, which also increase at higher speeds. This rotation speed is called runaway speed. Usually a turbine is designed to withstand the forces acting on it even at runaway speed, though this speed should never be reached.

The turbine blade tips should never reach supersonic speeds out of consideration of the strength required, although, if necessary, slight excess of the speed of sound might be permissible for a short time. This establishes the turbine runaway speed and thereby, the turbine's operating speed (rule of thumb: runaway speed = 2 × operating speed).

To keep turbine speed within the operating tolerance range, measures have to be taken to reduce it as soon as it exceeds the permissible operating speed, or – as a last resort – the plant must be shut down.

Pitch control. The blades are automatically oriented by control mechanisms so as to minimize torque in case of load shedding. If necessary, the blade pitch can be adjusted so far as to actively slowdown the turbine. Even if individual blades should not adjust their pitch, the braking torque of the remaining blades would be enough to slow the turbine down. Dr. Viktor Kaplan (1876–1934) had already patented a hydraulic turbine with adjustable blades in 1914 (Fig. 29). Such turbines, known as the Kaplan turbine, are used around the world today.

Only if – failing all precautions and redundancies – the turbine cannot be stopped by adjusting the blade pitch, another step has to be taken.

Blocking the flow. Like the hydroelectric power plant bulkheads that stop the flow of water and drain the turbine (e.g., for inspection), SUTs also have a blocking mechanism. But as air is approximately 1,000 times less dense than water, much less material is required for the solar tower. A "parachute" membrane is one option. Sliding doors similar to those used for airport hangars can also be used.

Physical Model

The exact description of the output behavior of a solar updraft tower under specific meteorological conditions and with specified tower height, tower diameter, and collector radius is only possible with a comprehensive thermodynamic and fluid dynamic finite elements computer program. It includes finding and describing the influence of heat transfer between the soil and the air in the collector, friction losses in the collector and the tower, and heat storage in the soil and output control, all of which can be very complex.

With certain simplifications, however, the basic concept and the influence of significant parameters on expected total plant efficiency and output can be seen in the following equations.

Generally speaking, power output P of the solar tower can be calculated as the solar input $\dot{Q}_{solar}$

Solar Updraft Towers. Figure 21
Elevation and layout from the finite elements model

Solar Updraft Towers. Figure 22
Deformation and stress distribution in the support structure (red = points of maximum stress)

multiplied by the respective efficiencies of collector, tower, and turbine(s):

$$P = \dot{Q}_{solar} \cdot \eta_{coll} \cdot \eta_{tower} \cdot \eta_{turbine} = \dot{Q}_{solar} \cdot \eta_{plant} \quad (1)$$

The solar energy input $\dot{Q}_{solar}$ into the system can be written as the product of global horizontal radiation G_h and collector area A_{coll}.

$$\dot{Q}_{solar} = G_h \cdot A_{coll} \quad (2)$$

The tower (chimney) converts the heat flow produced by the collector into kinetic energy (convection current) and potential energy (pressure drop at the turbine). Thus, the density difference of the air caused by the temperature rise in the collector works as a driving force. The lighter column of air in the tower is connected with the surrounding atmosphere at the base (inside the collector) and at the top of the tower, and thus acquires lift. A pressure difference Δp_{tot} is produced between tower base (collector outlet) and the ambient:

$$\Delta p_{tot} = g \cdot \int_0^{Htower} (\rho_a - \rho_{tower}) \cdot dH \quad (3)$$

Thus Δp_{tot} increases with tower height.

The pressure difference Δp_{tot} can be subdivided into a static and a dynamic component, neglecting friction losses:

$$\Delta p_{tot} = \Delta p_s + \Delta p_d \quad (4)$$

The static pressure difference drops at the turbines; the dynamic component describes the kinetic energy of the airflow.

With the total pressure difference and the volume flow of the air at $\Delta p_s = 0$, the power P_{tot} contained in the flow is now:

$$P_{tot} = \Delta p_{tot} \cdot v_{tower,max} \cdot A_{tower} \quad (5)$$

Solar Updraft Towers. Figure 23
Close relatives: horizontal solar tower turbine (left) and Kaplan turbine (right) (Source Kaplan turbine: VATECH Hydro)

Solar Updraft Towers. Figure 24
Turbine flow calculation mesh (IHS, University of Stuttgart)

from which the efficiency of the tower can be established:

$$\Delta_{\text{tower}} = \frac{P_{tot}}{\dot{Q}} \tag{6}$$

Actual subdivision of the pressure difference into a static and a dynamic component depends on the energy taken up by the turbine. Without turbine, a maximum flow speed of $v_{\text{tower, max}}$ is achieved, and the whole pressure difference is used to

Solar Updraft Towers. Figure 25
How the turbine housing influences the flow pattern

accelerate the air and is thus converted into kinetic energy:

$$P_{tot} = \frac{1}{2} \Delta \dot{m}\, v^2_{\text{tower, max}} \tag{7}$$

Using the Boussinesq approximation [14], the speed reached by free convection currents can be expressed as

$$v_{\text{tower, max}} = \sqrt{2 \cdot g \cdot H_{\text{tower}} \cdot \frac{\Delta T}{T_0}} \tag{8}$$

where ΔT is the temperature rise between ambient and collector outlet (=tower inflow).

Tower efficiency is given in equation 9 [8]:

$$\Delta_{\text{tower}} = \frac{g \cdot H}{c_p \cdot T_0} \tag{9}$$

This simplified representation explains one of the basic characteristics of the solar tower, which is that the tower efficiency is fundamentally dependent only on its height. For heights of 1,000 m, the deviation from the exact solution, caused by the Boussinesq approximation, is negligible.

Using equations (1), (2), and (9), it can be found that solar updraft tower power output is proportional to collector area and tower height, i.e., proportional to the cylinder depicted in Fig. 2.

As electrical output of the solar tower is proportional to the volume included within the tower height and collector area, the same output may result from a large tower with a small collector area and vice versa. As soon as friction losses in the collector are included in a detailed simulation, the linear correlation between power output and the product "collector area times tower height" is not strictly valid any more. Still, it is a good rule of thumb as long as the collector diameter is not too large.

Prototype

Detailed theoretical preliminary research and a wide range of wind tunnel experiments led to the establishment of an experimental plant with a peak output of 50 kW on a site made available by the Spanish utility Union Electrica Fenosa in Manzanares (about 150 km south of Madrid) in 1981/82 (Fig. 30), with funds provided by the German Ministry of Research and Technology (BMFT) [3, 6, 7].

The aim of this research project was to verify, through field measurements, the performance projected from calculations based on theory, and to examine the influence of individual components on

Solar Updraft Towers. Figure 26

Solar Updraft Towers. Figure 28
Flow pattern in the area of redirection. The figure shows speed profiles (*blue*: low speed, *red*: high speed)

the plant's output and efficiency under realistic engineering and meteorological conditions.

The main dimensions and technical data for the facility are listed in Table 1.

The tower comprises a guyed tube of trapezoidal sheets, gauge 1.25 mm and corrugation depth 150 mm. The tube stands on a supporting ring 10 m above ground level; this ring is carried by eight thin tubular columns, so that the warm air can flow in practically unhindered at the base of the tower. A prestressed membrane of plastic-coated fabric, shaped to provide good flow characteristics, forms the transition between the roof and the tower. The tower is guyed at four levels, and in three directions, to foundations secured with rock anchors. The tower was erected at ground level, utilizing a specially developed incremental lifting method: First, the top section of the tower was installed on a lifting ring on the ground, and then it was raised onto the supporting ring by means of hydraulic presses. Subsequently, the other sections were assembled on the ground, connected to the already installed top tower section(s), and then the whole assembly was lifted. So the complete tower was built in 20 shots of 10 m each.

The turbine (Fig. 31) is supported independently of the tower on a steel framework 9 m above ground level. It has four blades, which are adjustable according to the face velocity of the air in order to achieve an optimal pressure drop across the turbine blades.

Vertical wind velocity is 2.5 m/s on start-up and can attain a maximum of 12 m/s during turbine operation.

The collector roof of the solar tower not only has to have a transparent or translucent covering, it must also be durable and reasonably priced.

A variety of types of plastic sheet, as well as glass, were selected in order to determine which was the best – and in the long term, most cost effective – material (Fig. 32).

Solar Updraft Towers. Figure 29

Dr. Viktor Kaplan's US patent for a hydraulic turbine with adjustable blades (Source: European Patent Office)

Glass resisted heavy storms for many years without harm and proved to be self-cleaning thanks to the occasional rain showers.

The plastic membranes are clamped to a frame and stressed down to the ground at the center by use of a plate with drain holes. The initial investment cost of plastic membranes is lower than that of glass; however, in Manzanares the membranes got brittle with time and thus tended to tear. Material (temperature and UV stability) and design improvements (e.g., membrane domes) achieved in the last years may help to overcome this particular disadvantage.

Completion of the construction phase in 1982 was followed by an experimental phase, the purpose of which was to demonstrate the operating principle of a solar tower. The goals of this phase of the project were (1) to obtain data on the efficiency of the technology developed, (2) to demonstrate fully automatic, power-plant-like operation with a high degree of reliability, and (3) to record and analyze operational behavior and physical relationships on the basis of long-term measurements.

In Fig. 33, the main operational data, i.e., solar insolation, updraft velocity, and electric power output, are shown for a typical day. Two things shall be pointed out: Firstly, that power output during the day correlates closely with solar insolation for this small plant without additional storage. But, second, there is still an updraft during the night, which can be used to generate power during some hours of the night.

Solar Updraft Towers. Figure 30
Aerial photo of SUT prototype in Spain

Solar Updraft Towers. Table 1 Main dimensions and technical data of the Manzanares prototype

Tower height	194.6 m
Tower radius	5.08 m
Mean collector radius	122.0 m
Mean roof height	1.85 m
Number of turbine blades	4
Turbine blade profile	FX W-151-A
Blade tip speed to air transport velocity ratio	1:10
Operation modes	Stand-alone or grid connected mode
Typical collector air temperature increase	$\Delta T = 20$ K
Nominal output	50 kW
Collector covered with plastic membrane	40,000 m^2
Collector covered with glass	6,000 m^2

With increasing collector size, i.e., generally speaking with increasing thermal inertia of the system, this effect increases, as will be seen later from the results of simulation runs for large-scale plants (Fig. 34).

In order to arrive at a thorough understanding of the physical relationships and to evolve and identify points of approach for possible improvements, a computer simulation code was developed that describes the individual components, their performance, and their dynamic interaction. This program was verified on the basis of experimental measurement results from Manzanares. Today, it is a development tool that takes all known effects into account and with the aid of which the thermodynamic behavior of large-scale plants under given meteorological conditions can be calculated in advance [7, 21].

From mid-1986 to early 1989, the plant was run on a regular daily basis. As soon as the air velocity in the tower exceeded a set value, typically 2.5 m/s, the plant started up automatically and was automatically connected to the public grid. During this 32-month period, the plant ran, fully automatically, an average of 8.9 h per day. In 1987, there were 3,067 h with a solar global horizontal irradiation of over 150 W/m^2 at the Manzanares site. Total operation time of the plant with net positive power to the grid was 3,157 h, including 244 h of net positive power to the grid at night.

These results show that the system and its components are dependable and that the plant as a whole is capable of highly reliable operation. Thermodynamic

Solar Updraft Towers. Figure 31
Turbine of prototype SUT, three of the four fast-moving blades can be seen (view from below the turbine up to the tower top)

Solar Updraft Towers. Figure 32
Collector types tested (*left*: glass, *right*: plastic sheet)

inertia is a characteristic feature of the system, continuous operation throughout the day is possible, and for large systems, even abrupt fluctuations in energy supply are effectively cushioned.

Using the custom-made thermodynamic simulation code based on finite elements that solves the equations for conservation of energy, momentum, and mass, the theoretical performance of the plant was calculated and the results compared with the measurements obtained. The code includes simulation of collector performance based on standard collector theory [22], extended by an integration of thermal storage effects of the natural collector ground and – if required – additional thermal storage by water-filled bags into the model [13, 23]. Fluid dynamics of collector, turbine, and tower are calculated, taking into consideration friction in the respective system components. Calculation of pressure losses relies on standard calculation procedures [24] and, where this is considered not to be applicable or sufficient, on experimental

Solar Updraft Towers. Figure 33
Main operational data for a typical day

Solar Updraft Towers. Figure 34
Results of simulation runs for a large plant with additional thermal storage, for a site with pronounced seasonal variations

data including wind tunnel tests. Turbine behavior is modeled based on the CFD design calculations done by the "Institute of Fluid Dynamics and Hydraulics Machinery" of the University of Stuttgart [25].

Figure 35 shows a comparison between the measured and calculated average monthly energy outputs, showing that there is good agreement between the theoretical and measured values.

Solar Updraft Towers. Figure 35
Comparison between measured and calculated average monthly energy output

Overall, it may be said that the optical and thermodynamic processes in a solar tower are well understood and that models have attained a degree of maturity that accurately reproduces plant behavior under given meteorological conditions.

Transferring the Results to Large-Scale Plants

Detailed investigations, supported by extensive wind tunnel experiments, show that thermodynamic calculations for collector, tower, and turbine are very reliable for large plants as well.

Despite considerable area and volume differences between the Manzanares pilot plant and a projected 100-MW facility, the key thermodynamic factors are of similar size in both cases. Using the temperature rise and air velocity in the collector as examples, the measured temperature rise at Manzanares was a daily average of 8 K, wind speed was average 4 m/s, while the corresponding calculated average figures for a 100-MW facility are 11 K and 9 m/s.

Therefore measurements taken from the experimental plant in Manzanares and solar updraft tower thermodynamic behavior simulation codes are used to design large plants with an output of up to 200 MW.

In this way, the overall performance of the plant, by day and by season, given the prescribed plant geometry and climate, considering all physical phenomena including single and double glazing of the collector, heat storage system, and pressure losses in collector, tower, and turbine, can be calculated rather accurately.

Large-Scale Solar Updraft Towers

General System Advantages

Apart from working on a very simple principle, solar updraft towers have a number of special features:

1. The collector can use all solar radiation, both direct and diffuse. This is crucial for tropical countries where the sky is frequently overcast.
2. Due to the soil under the collector working as a natural heat storage system, solar updraft towers will operate 24/7 on pure solar energy, at reduced output at night time. If desired, additional water tubes or bags placed under the collector roof absorb part of the radiated energy during the day and release it into the collector at night. Thus solar updraft towers can operate as base load power plants. As the plant's prime mover is the air temperature *difference* (=air density difference) between the air in the tower and ambient air, lower ambient temperatures at night help to keep the output at an almost constant level even when the temperature of natural and additional thermal storage also decreases without sunshine, as the temperature *difference* remains practically the same.

Solar Updraft Towers. Table 2 Typical dimensions and electricity output

Capacity		50 MW	100 MW	200 MW
Tower height	m	750	1,000	1,000
Tower diameter	m	90	110	120
Collector diameter	m	3,750	4,300	7,000
Electricity output at 2,300 kWh/(m^2yr)[a]	GWh/a	153	320	680
Electricity output at 1,800 kWh/(m^2yr)[b]	GWh/a	120	250	532

[a]Annual global horizontal solar radiation of 2,300 kWh/(m^2a), a value found at the best sites worldwide
[b]Annual global horizontal solar radiation of 1,800 kWh/(m^2a), a typical value for Spain

3. Solar updraft towers are particularly reliable. Turbines and generators – subject to a steady flow of air – are the plant's only moving parts. This simple and robust structure guarantees operation that needs little maintenance and of course no combustible fuel.
4. Unlike conventional power stations (and also some other solar thermal power station types), solar updraft towers do not need cooling water. This is a key advantage in the many sunny countries that already have major problems with water supply.
5. The building materials needed for solar updraft towers, mainly concrete and glass, are available everywhere in sufficient quantities. In fact, with the energy taken from the solar tower itself and the stone and sand available in the desert, they can be reproduced partly on site.
6. Solar updraft towers can be built now, even in less industrially developed countries. The industry already available in most countries is entirely adequate for solar updraft tower requirements. No investment in high-tech manufacturing plants is needed.
7. Even in less developed countries, it is possible to build a large plant without high foreign currency expenditure by using local resources and work force; this creates large numbers of jobs while significantly reducing the required capital investment and thus the cost of generating electricity.

Solar Updraft Towers. Table 3 Investment cost and electricity cost

Capacity		50 MW	100 MW	200 MW	
Tower cost	Mio. €	72	156	188	188
Average labor cost for collector construction		18 €/h	18 €/h	18 €/h	5 €/h
Collector cost	Mio. €	140	166	388	320
Turbine cost including housing	Mio. €	56	80	146	146
Engineering, tests, miscellaneous	Mio. €	32	45	49	48
Total investment cost	Mio. €	300	447	771	702
Annuity on investment	Mio. €/a	28.1	41.9	72.2	65.7
Annual operation and maintenance cost	Mio. €/a	1.6	2.3	3.7	3.7
Electricity cost at 2,300 kWh/(m^2yr)[a]	€/kWh	0.19	0.14	0.11	0.10
Electricity cost at 1,800 kWh/(m^2yr)[a]	€/kWh	0.25	0.18	0.14	0.13

[a]Using an average interest rate of 8% and a depreciation time of 25 years

Nevertheless, solar updraft towers also have a feature that makes them less suitable for some sites: They require large areas of flat land. This land should be available at low cost, which means that there should be no competing usage, e.g., intensive agriculture for the land. The siting of the solar updraft tower has to be carefully considered in extremely earthquake prone areas.

Electricity Generation Costs

Electricity yielded by a solar updraft tower is in proportion to the intensity of global solar radiation, collector area, and tower height. There is in fact no

Solar Updraft Towers. Figure 36
Levelized electricity costs vs. average cost of capital for solar updraft towers (high-insolation, low labor cost country)

optimum physical size for such plants. Optimum dimensions can be calculated only by including specific component costs (collector, tower, turbines) for individual sites. And so plants of different optimum key dimensions will be built for different sites – but always at optimum cost: If collector area is cheap and concrete expensive, then the collector will be large and the tower relatively small; if the collector is expensive, there will be a smaller collector and a tall tower.

To give an overview, typical dimensions for selected solar updraft tower capacities are given in Table 2. The numbers are based on typical material and construction costs.

Based on specific costs and the dimensions from Table 2, investment costs were calculated. For the 50-MW solar updraft tower, for example, investment costs of 300 M€ are estimated (see Table 3).

With the respective annual energy outputs from simulation runs, electricity costs (EC) are calculated using an average cost of capital (interest rate) of 8% and a depreciation time of 25 years. Results are shown in Table 3 for a 50-MW, a 100-MW, and a 200-MW power plant. For all plants, two generic reference sites are considered with an annual global horizontal insolation of 1,800 and 2,300 kWh/(m^{2}yr), respectively, to show the effect of this important site characteristic (bottom rows of Table 2 and Table 3). For the 200-MW solar updraft tower, there is an additional column to the very right with data assuming average labor cost of 5 €/h, as compared to the value of 18 €/h being used before. An average labor cost for collector construction of 5 €/h, or even significantly below, can be expected in low-wage countries, e.g., North Africa, Mexico, or China.

From Table 3 and Fig. 36, it becomes obvious that with increasing plant size, a significant reduction of electricity generation cost is associated, leading to EC of 0.11 €/kWh for a 200-MW plant at a high-insolation site, with a further reduction in low-wage countries of about half a €-Cent (see examples given in Table 3).

The financial parameters interest rate and depreciation time are varied to illustrate their influence (Fig. 36). The upper boundary was calculated for a depreciation time of 20 years, the lower boundary for 30 years. As expected, electricity generating costs of the capital intensive solar updraft towers are dominated by interest rate. Depreciation time has a significant influence, too. Assuming an average interest rate of, e.g., 12% and a depreciation time of 20 years leads to EC of 0.14 €/kWh for the 200-MW system at a location with 2,300 kWh/(m^{2}yr) of global solar radiation and average collector labor costs of 5€/h. When, e.g., by clever financial engineering, an interest rate of 5% and a depreciation time of 30 years is achieved, EC drop to 0.07 €/kWh, i.e., half the formerly calculated value.

Future Directions

Designing and building such large structures as solar updraft towers cost efficiently is a challenge, but

finding investors for the construction of solar updraft towers is the main hurdle today. The risk margins an investor puts on top of the "normal" interest rate when investing into this nonproven technology are high and therefore prevented all commercial projects until today. What is missing is a medium-scale power plant in the, say, 1–10 MW range to make SUTs a proven technology. Small-scale solar updraft towers are not economically viable today. Only large plants with a capacity of 100 MW or more are characterized by power generation costs that are competitive (cf. Fig. 36).

The only way to overcome this vicious circle is a considerable subsidy for the first large plant by a government, a foundation, or similar. So today, it is not clear if a large scale solar updraft tower will ever be built.

If they will ever be built, there are various fields to further improve the technology and adapt it to the needs of electricity consumers:

- Higher towers may further reduce electricity generation costs.
- Better control mechanisms, strategies, and algorithms will help to closely match the power generation curve to the demand curve.
- Water production by either using the collector roof as a giant rain catcher or condensation of water vapor inside the SUT as part of the process may help to provide water in arid areas.

Glossary

Anomaly The deviation of a parameter from its mean value over a defined reference period.

Blackbody radiator A body that emits the maximum radiation possible for its temperature, at all wavelengths.

Chromosphere The lower solar atmosphere, within about 2,000 km of the photosphere.

Cloud condensation nuclei An aerosol particle or air ion on which water can condense such that it grows into a cloud water droplet.

Diffuse fraction The ratio of the intensity in shade divided by the intensity in direct sunlight; for clear skies the diffuse fraction approaches zero, whereas for cloudy skies (and/or with heavy aerosol loading) the diffuse fraction approaches unity.

El Niño Southern Oscillation (ENSO) The extremes of this quasi-periodic (period of 3–7 years) coupled ocean–atmosphere circulation oscillation are El

Niño and La Niña events in which the sea surface temperature in the equatorial Pacific is, respectively, warmer and colder than average. ENSO is one of the predominant causes of interannual variability of regional climates around the globe.

Forbush decrease A transient decrease in GCR fluxes reaching Earth lasting typically 1–4 days, caused by the shielding properties of transient events released from the solar atmosphere.

Galactic cosmic rays (GCRs) Charged particles ranging in mass from electrons and protons up to iron and silicon ions with energies typically of order 0.1–100 GeV. They are generated by explosive galactic events such as supernovae. The flux of GCRs at Earth is modulated by the extension of the solar magnetic field into interplanetary space.

Global albedo (A) The fraction of the total electromagnetic energy from the Sun incident on the Earth that is reflected back into space.

Global circulation model (GCM) Also called a General Climate Model. A numerical model of Earth's global climate system incorporating best available knowledge of the fluid dynamical, chemical, and, increasingly, biological aspects of Earth's climate system.

Global Mean Air Surface Temperature (GMAST) The average of the temperature measured 2 m above the ground by a global network of meteorological stations. The number of stations available declines further back into the past and is consistently lower in the southern hemisphere. Note that it is usually expressed as an anomaly by taking global averages of the station temperature anomalies.

Heliosphere The area of space surrounding the Sun and solar system dominated by the solar wind and the magnetic field of solar origin embedded in it.

Jet stream Narrow bands of fast westerly (eastward) wind in the upper troposphere caused by the combination of equatorial solar heating and Earth's rotation. There are two in each hemisphere: the polar jets are typically found at latitudes of 30–60° whereas the weaker subtropical jets are at 25–30°.

Laschamp event An example of a geomagnetic excursion that occurred around 40 kyr ago. These events are "short-lived" (typically 1–10 kyr in duration) decreases in the geomagnetic field intensity (often to below 20% of normal) with a variation in pole orientation of up to 45°, but no polarity reversal. Any confirmed and consistent paleoclimate signatures of climate change associated with this event would be very significant because the GCR flux reaching Earth's atmosphere would increase but with no simultaneous solar irradiance change.

North Atlantic Oscillation (NAO) An oscillation in the pattern and strengths of westerly winds and storm tracks in the north Atlantic. It is quantified by the fluctuations in sea level pressure between the Icelandic low and the Azores high. The NAO is very closely related to the Arctic Oscillation (AO – which is also called the Northern Annular Mode, NAM).

Northern annular mode (NAM) Also called the Arctic Oscillation: see "North Atlantic Oscillation."

Open solar flux The magnetic field of solar origin that leaves the top of the solar atmosphere and fills the heliosphere.

Paleoclimatology The reconstruction of past climate from a variety of sources such as tree growth from tree rings (dendrochronology); analysis of air bubbles trapped in snow and ice; chemical and isotopic analysis of speliothems, lake deposits, ocean sediments, ice-rafted debris and corals; and documentary evidence.

Photosphere The visible surface of the Sun (mean radius $R_\odot$).

Radiative forcing The change in the difference between the incoming radiation energy and the outgoing radiation energy per unit area at the atmospheric boundary between the troposphere and the stratosphere (the tropopause). It is measured in Wm^{-2}. Consider the case of a TSI change of ΔS: the change in the total power incident on Earth is $\Delta S \pi R_E^2$, where R_E is a mean Earth radius. The change per unit surface area of the Earth is $\Delta S \pi R_E^2/(4\pi R_E^2) = \Delta S/4$. The part not reflected back into space is $\Delta S(1 - A)/4$, where A is Earth's global albedo. Therefore, a TSI change of ΔS corresponds to a radiative forcing of $\Delta S(1 - A)/4$. For other influences on climate the equivalent value can be computed in each case.

Solar energetic particles (SEPs) Charged particles ranging in mass from electrons and protons up to iron and silicon ions of energies of order 0.1–100 MeV. They are generated by transient events in the solar atmosphere and heliosphere.

Solar wind The continuous, supersonic and super Alfvénic outflow of thermal plasma (ionized gas) from the solar atmosphere driven by its high temperatures.

Spectral solar irradiance (SSI) The solar electromagnetic power at a given wavelength, per unit wavelength, falling on unit area normal to the Sun–Earth line (often considered in the UV band of the spectrum).

Stratosphere Atmospheric layer at about 20–55 km altitude, between the tropopause and the stratopause.

Super-Alfvénic In a plasma (ionized gas) a family of waves which modulate both the plasma and the magnetic field can propagate. These are called Alfvén waves, and particles that move faster than them are called Super-Alfvénic.

Total solar irradiance (TSI) The total solar electromagnetic power falling on unit area normal to the Sun–Earth line.

Troposphere The Atmospheric layer between Earth's surface and the tropopause, which lies at an altitude of about 11 km at the poles and 17 km at the equator. All climate and weather processes reside in the troposphere.

Definition

Solar electromagnetic radiation powers Earth's climate system and, consequently, it is often naively assumed that changes in this solar output must be responsible for changes in Earth's climate. However, the Sun emits according to its surface temperature and the huge thermal time constant of the outer part of the Sun limits the variability in surface temperature and hence output. As a result, on all timescales of interest, changes in total power output are limited to small changes in effective surface temperature (associated with magnetic fields) and potential, although as yet undetected, solar radius variations. Larger variations are seen in the UV part of the spectrum which is emitted from the lower solar atmosphere (the chromosphere) and which influences Earth's stratosphere. There is interest in "top-down" mechanisms whereby solar UV irradiance modulates stratospheric temperatures and winds which, in turn, may influence the underlying troposphere where Earth's climate and weather reside. This contrasts with "bottom-up" effects in which the small total solar irradiance (dominated by the visible and near-IR) variations cause surface temperature changes which drive atmospheric circulations. In addition to these electromagnetic outputs, the Sun modulates energetic particle fluxes incident on the Earth. Solar Energetic Particles (SEP) are emitted by solar flares and from the shock fronts ahead of supersonic (and super-Alfvénic) ejections of material from the solar atmosphere. These SEPs enhance the destruction of polar stratospheric ozone which could be an additional form of top-down climate forcing. Even more energetic are Galactic Cosmic Rays (GCRs). These particles are not generated by the Sun, rather they originate at the shock fronts emanating from violent galactic events such as supernovae explosions; however, the expansion of the solar magnetic field into interplanetary space means that the Sun modulates the number of GCRs reaching Earth. These play a key role in enabling Earth's global electric (thunderstorm) circuit and it has been proposed that they also modulate the formation of clouds. Both electromagnetic and corpuscular solar effects are known to vary over the solar magnetic cycle which is typically between 10 and 14 years in length (with an average close to 11 years). The solar magnetic field polarity at any one phase of one of these activity cycles is opposite to that at the same phase of the next cycle and this influences some phenomena, for example GCRs, which therefore show a 22-years ("Hale") cycle. Other phenomena, such as irradiance modulation, do not depend on the polarity of the magnetic field and so show only the basic 11-year activity cycle. However, any effects on climate are much more significant for solar drifts over centennial timescales. This chapter discusses and evaluates potential effects on Earth's climate system of variations in these solar inputs. Because of the great variety of proposed mechanisms, the wide range of timescales studied (from days to millennia), and the many debates (often triggered by the application of inadequate statistical methods), the literature on this subject is vast, complex, divergent, and rapidly changing: consequently the number of references cited in this review is very large (yet still only a small fraction of the total).

Introduction

It is interesting to ponder what the author h-index of the astronomer Sir Frederick William Herschel

(1738–1822) would be (an author with an h-index of *n* means he/she has authored *n* publications each of which has been cited in other publications at least *n* times). Certainly his 1801 paper [1], in which he speculated on a connection between sunspots and the regional climate of the UK, has been cited a great many times and continues to be cited regularly today. Herschel appears to have been more aware of the limitations of his apparent correlation (writing "this prediction ought not to be relied on by anyone") than many who have subsequently cited his paper. He notes limitations to his speculation that many subsequent studies of solar influence on climate have failed to adequately consider. Specifically:

1. Sunspots are, at best, only indirectly related to the solar outputs that are relevant to climate. (Hershel attempts to build an argument about enhanced emission from sunspots which is now known to be incorrect.)
2. The lack of suitable measurements of Earth's global climate leads to the use of indirect proxies (Herschel used the price of wheat) and there are many other factors which can influence such proxies. (Note that some modern studies continue to try to use the price of wheat as a climate proxy [e.g., 2].)
3. The datasets are not homogeneous and measurements show instrumental drifts and discrete jumps. (Herschel notes this in respect of the sunspot data available to him.)
4. The climate data are usually regional and not global. (Herschel used the price of wheat in the UK and not on the global market.)
5. The climate data are often for a limited season (in Herschel's case, this is effectively the growing season of wheat).
6. Correlations readily occur by chance and the probability of that happening must be evaluated. In geophysics (including climate science) this test must allow for the "persistence" in the data time series. Also called "conservation," this is a measure of the tendency of one data point to be similar to its predecessors, and it lowers the effective number of independent samples and hence the significance of any correlation. In addition, tests are needed to prevent "data snooping," i.e., exploiting a feature in the data that turns out to be a statistical or instrumental artifact. To ensure wrong conclusions are not drawn from statistical coincidences, clear null hypotheses must be formulated and proper statistical tests performed [3, 4].
7. Even when the proxies are reliable indicators of a climate variable, there are a great many other influences on it besides solar variability. For example, Herschel neglected the effects of volcanic eruptions that occurred during the interval that he studied. Multiple regression analysis is often used [5–7] but it can be misleading if intercorrelations exist between the data series that are input into the study or if genuine factors are omitted. Naive regression analyses may also be misleading due to convoluted nonlinear response associated with feedback processes, the use of non-optimal regression techniques, and the presence of internal system variability [8], particularly arising from ocean circulation changes [9]. Hence such results need to be interpreted with caution and judgment.
8. The potential for selection effects mean one must ask "would the correlation coefficient be as high if an equivalent dataset were substituted?" (For example, in Herschel's case, was the behavior of the price or barley similar to that of wheat?) Selection effects can often arise (unintentionally or otherwise) from restricted data intervals. For example, Lockwood and Fröhlich [10] showed that whereas solar irradiance and cosmic ray trends before 1985 had been in the direction needed to explain the observed global temperature rise, after that date (which marks the peak of a grand solar maximum [11]) they have been in the opposite direction. Hence, studies based only on data from before 1985 are more likely to be misleading.
9. Even a statistically significant correlation or detected periodic signal does not establish causality. Neither do lags and phases for coupled systems involving stationary oscillations. There are a huge number of publications looking at oscillations at periods close to that of the solar cycle and/or correlations with the solar cycle at a fixed lag. Tests of some of these reveal that they are unlikely to be driven by solar forcing, and that they are more likely to reflect other natural cycles of the

climate system, such as the 14-year cycle, or a harmonic combination of multi-year cycles [12, 13].

10. Is there a realistic mechanism or series of mechanisms that could have given rise to the correlation? (Herschel's proposal invoked solar physics, climate science, agricultural science, and the effect of supply-and-demand in economics.)

The reason why the citation rate for Herschel's speculation is so high is that a great many subsequent studies have explored the same ideas. The growth in modern-day interest can be traced to John A. "Jack" Eddy (1931–2009). (Incidentally, Eddy's h-index is known and is just 13, but his most influential paper, published in 1976 [14], has been cited 797 times at the time of writing – citation analysis using Web of Science, May 2010.) The academic reputation of the field of Sun–climate relations is poor because many, perhaps most, studies do not address all, or even some, of the limitations listed above. It is also a field that in recent years has been corrupted by unwelcome political and financial influence as climate change skeptics have seized upon solar effects as an excuse for inaction on anthropogenic effects. In particular, figures and statistics with known errors, limitations, and inaccuracies are repeatedly reproduced on the internet and in the media [15]. None of this makes any difference to the scientific reality, or otherwise, of mechanisms connecting solar variability and Earth's climate; however, it does make evaluation of the evidence much more difficult. Recent reviews have been presented by Reid (2000), Rind (2002), Haigh (2003, 2007), Beer (2006), Foukal et al. (2006), de Jaeger (2008), and Gray et al. (2010) [16–23].

Solar Variability

Solar outputs reaching Earth undergo periodic variations over a range of time scales. These include the 27-day variation due to solar rotation, the decadal-scale solar magnetic (sunspot), and Hale cycles and oscillations between grand solar maxima and minima on timescales of several centuries. How a key climate parameter, such as the Global Mean Air Surface Temperature (GMAST), varies in response to these solar variations will depend on its response timescales. Estimates of the GMAST response time have varied from less than 1 year to several decades [24–34]. Knutti et al. [28] discuss the time constants of different parts of the climate system: short time scales (1 year or less) apply to atmospheric adjustments and land surface processes, medium time scales (of order decades) to the melting of sea ice, and long time scales (many decades) to warming of the whole ocean surface layer. Ocean warming effects are complex because of mixing behavior [29, 30]. In the absence of heat uptake by ocean circulations, diffusion through the upper ocean layers leads to a spectrum of GMAST response times (rather than a single value) up to about 20 years [28, 299]. However, an estimated 40–50% of heat uptake is by deeper meridional circulation and this has a much longer (>500 years) response time [298]. Climate response modeling [31] and analysis of preindustrial data [32, 33] has yielded effective response times of up to 10 years. Hence, it is clear that responses to 27-day solar variations will be damped to undetectable levels in GMAST whereas the centennial solar variations should be reflected in ocean surface layer temperatures. The extent to which the solar cycle variations will be damped is still a matter of debate. Lockwood and Fröhlich [11] showed that solar trends since 1985 have been in the opposite direction to that needed to explain the observed GMAST rise. This could be explained by solar forcing only (with large amplification) using a very long (of order several decades) response time, but without shorter response times and this would also mean that all associations of decadal-scale oscillations in GMAST with the solar cycle were coincidental as the true solar cycle signal would be highly damped [34]. Hence there is a paradox: attributing large fractions of the centennial global warming to solar changes means that decadal-scale correlations on global scales must be regarded as coincidences, whereas accepting the validity of evidence for a solar cycle global climate response would mean that recent climate trends were not related to solar changes. This does not mean that components of the global system, which may have a shorter response time than GMAST, would not show solar cycle variations.

Elsewhere in this section on Solar Radiation, the article by Fröhlich discusses the observations of total solar irradiance (TSI) covering three solar cycles. This variability is well explained by the effects of magnetic

structures threading the photosphere [35, 37], i.e., the darkening effect of sunspots and the brightening effect of smaller magnetic flux tubes called faculae. To evaluate the solar contribution of TSI variability to centennial climate change requires its reconstruction over the past few centuries. Figure 1 shows a collection of TSI reconstructions covering the interval from just before the Maunder minimum (the period in the second half of the seventeenth century when almost no sunspots were seen) up to the present day. The figure shows that estimates of the magnitude of the centennial drift in TSI have declined: initial estimates [38–40] were based on a limited survey of putative Sun-like stars [36, 49]. However, larger surveys with stricter criteria for Sun-like stellar analogues did not reproduce the key result employed in these early TSI reconstructions [50, 51]. As a result, information on long-term drift of the solar magnetic field from geomagnetic activity [11, 45, 52] was employed in the later reconstructions. Reliable geomagnetic activity data are available back to 1868 and can be used to derive the open solar flux (OSF), the magnetic flux leaving the top of the solar atmosphere. OSF correlates well with TSI over the solar cycle [42, 53] and recent studies indicate that observed TSI may also reflect some of the longer-term drift in OSF [43]. Modeling of the OSF variation [54–58] showed that the total flux threading the photosphere could be constrained by the OSF variation and this could be combined with sunspot observations to reconstruct TSI back to 1600. Figure 1 shows that these second methods are yielding considerably smaller changes in TSI since the Maunder minimum than the early reconstructions based on stellar analogues.

In evaluating some reported associations between TSI and climate, it is important to note the implications of the debate about the intercalibration of TSI data across the "ACRIM gap" in modern TSI data composites (see Fig. 1 in the article by Fröhlich), after the end of the available data from the ACRIM1 space-based radiometer but before its successor, ACRIM2,

Solar-Induced Climate Effects. Figure 1

Reconstructions of past variations in TSI using different solar proxies. The Hoyt and Schatten (1993) [38] estimates are based on solar cycle length, L. Solanki and Fligge (1999) [39] used the annual sunspot number, R (available back to 1713, the *dotted line*). Lean et al. (1995) [40] and Lean (2000) [69] used a combination of the group sunspot number R_G (available back to 1611), and its 11-year running mean. In these early reconstructions, the amplitude of the slowly-varying component was derived by comparison of the modern-day Sun and Maunder minimum Sun to distributions of the luminosity of cyclic and noncyclic Sun-like stars. Lockwood and Stamper (1999) [53] used the observed correlation between the variations of TSI and the open solar flux on decadal timescales [42]. Wang et al. (2005) [58] used a solar magnetic flux transport model constrained to fit the observed open solar flux variation [11, 45]. Foster (2004) [46] and Lockwood (2004) [47] used Greenwich sunspot observations (available back to 1874). Krivova et al. (2007) [48] used R_G and the open solar flux variation

started to take data. These composites use many of the same raw data series but differ in the degree to which they allow for instrument degradation and in the instrument intercalibrations. Lockwood and Fröhlich [34] note that the anticorrelation between TSI and GCR fluxes (see below) is found for the reconstructed TSI data time series known as the "PMOD data composite" but does not hold for the alternative "ACRIM" composite [44, 59]. Scafetta and Willson (2009) [60] argue that the long-term reconstruction of TSI by Krivova et al. (2007) [48] supports the ACRIM composite but Krivova et al. (2009) [61], and Wenzler et al. (2009) [62] point out that the more precise TSI reconstruction from modern magnetograph data is inconsistent with the ACRIM composite but consistent with the PMOD composite. The implications of this debate are discussed later in relation to Fig. 2.

The UV part of the solar spectrum is much more variable than TSI and is an essential factor that modulates ozone abundance, temperatures, and winds in Earth's stratosphere (see review by Gray et al. [23]). Composites of UV spectral solar irradiance (SSI) had shown little variation in the spectral shape, such that different wavelengths exhibit a similar waveform to TSI [68, 69] and this has been reflected in centennial reconstructions of SSI [63]. However, recent observations of the descent into the current unusual solar minimum [41] cast doubt on this as they show more variability in the UV and considerable change in spectral shape [67], although the validity of these data has been questioned [70]. If valid, they imply that at the wavelengths responsible for stratospheric modulation, centennial variation may be greater than previously thought [72]. There is debate about the degree of centennial drift in historic observations of the UV Ca "K" absorption line [71, 73, 74] but this may, anyway, be of limited relevance because the absorption arises higher in the solar atmosphere than does the UV continuum emission.

The degree of uncertainty in long-term variability of TSI and SSI should be noted. Reconstructions allow for the effect of large active regions (groups of dark sunspots surrounded by bright faculae) which vary with the decadal- and centennial-scale changes in the large-scale solar dynamo. However, the long-term variability and effect of small-scale fields in the quiet Sun (away from active regions) driven by the turbulent, small-scale dynamo [75] is not well known. Furthermore, it has been suggested that magnetic fields below the solar surface may have an influence [76] and although the success of modeling TSI variations using surface fields means there is no evidence for these "shadow effects" over recent solar cycles, this does not necessarily mean that they could not have an effect on longer timescales. Another potential source of additional long-term drift arises from changes in the solar radius, $R_\odot$. A great many studies over many years have searched for such variations, both over recent solar cycles and, using eclipse data, on centennial timescales. These studies are inconclusive and often contradictory: it is unclear that any changes detected are bigger than the experimental uncertainties. For example, there are a number of reports that $R_\odot$ increases with solar activity [77] whereas other measurements show the reverse or no consistent change [78, 79]. Bruls and Solanki (2004) [80] demonstrated that surface luminosity features can perturb many techniques and the results from helioseismology show small and inconsistent changes [81]. The best observations place an upper limit of about 0.01% on variations in $R_\odot$ over decades [82–84] and reports of larger changes (e.g., [85]) remain controversial.

As well as being used in reconstructions of TSI, the OSF is highly anticorrelated with the flux of GCRs incident on Earth [87]. As discussed later, GCRs have been proposed as a direct modulator of Earth's climate; however, the anticorrelation of GCRs with OSF and irradiance means that GCRs may just be a proxy indicator of TSI and SSI variations. Indeed, the cosmogenic isotopes that GCRs produce are routinely used in paleoclimate studies as a proxy indicator of irradiance [87]. Lockwood [89] showed that the relationship between cosmogenic isotope production and TSI is monotonic but may not be linear, depending on the effect of unknowns in the long-term irradiance behavior discussed above. Steinhilber et al. [90] have recently reconstructed TSI variability on centennial scales using cosmogenic isotope data and for recent centuries their results are similar to the modern TSI reconstructions shown in Fig. 1. A number of cosmogenic isotope data sequences have been generated [91–93]. A key point to note is that the Maunder minimum is just one of a number of "grand solar minima" (and far from the deepest one in the record over the last 10^4 years),

Solar-Induced Climate Effects. Figure 2

Estimates in the literature of the contributions of solar change to observed global temperature rise vary widely. The *blue line* shows the global mean surface temperature (GMAST) anomaly compiled from observations by NASA/GISS [64], the *red line* the equivalent HadCRUT3v compilation by UEA and the UK Meteorological Office [65]. (Both GISS and HadCRUT3v have here been re-normalized to a reference period of 1900–2000.) The *black* and *grey lines* are estimates of the solar contribution from multivariate fits by Scafetta [66]: these employ only solar forcing and use as input the TSI reconstruction of Krivova et al. (2007) [48] (see Fig. 1), splined to different data composites of modern-day TSI measurements. The black curve (S-09A) is consistent with the ACRIM data composite whereas S-09C (in *grey*) is consistent with the PMOD data composite. The *green line* is the fit by Benestad and Schmidt [8] from full GCM modeling of all known climate forcings, the solar contribution to which is shown in mauve. The main issue is not so much the closeness of fit, it is the robustness and appropriateness of the procedures used, as discussed in the text. Only robust procedures have predictive power which is the key test of all science. Note the effect of extreme sensitivity of the solar-only multivariate fit to small features and hence the potential for "data snooping": the fit to the data after 1990 of the S-09A curve relies on the ACRIM composite which differs from the PMOD by what many believe to be a single (and rather small) erroneous calibration skip during the so-called ACRIM gap (see Lockwood and Fröhlich 2007 [35]). Using the PMOD composite (S-09C), the limitations of the multivariate fit begin to become apparent after around 1985 (with the oppositely-directed solar and GMAST trends noted by Lockwood and Fröhlich [10]). The fits of Scafetta [66] continue up to 2002: the subsequent exceptionally low solar minimum reveals that even curve S-09A will have a downward trend after 1997 and it too fails to reproduce the most recent GMAST data [67]

whereas modern space-based measurements are all within a "grand solar maximum." There has been debate as to the degree to which the current grand maximum is an exceptional one in terms of its amplitude [94, 95]. However, it is clear that its duration is relatively long and hence a return to more average solar conditions is somewhat overdue [96]. The OSF variation suggests that this decline commenced around 1985 [10, 11] and that the recent solar minimum (between cycles 23 and 24), which was exceptionally low compared to previous examples during the space age [41], is a symptom of that decline. From the composite of cosmogenic isotope records by Steinhilber et al. [93], Lockwood [41] estimates that there is about an 8% chance of a rapid return to Maunder minimum conditions within the next 50 years.

One last solar output is the continuous, but highly variable, stream of low-energy thermal particles in the solar wind which has been invoked in some climate studies (e.g., [97, 98]). The power incident on Earth's atmosphere delivered by the solar wind is smaller than that from solar electromagnetic radiation by a factor of between 10^4 and 10^5 [47]. Nevertheless, energy extracted from the solar wind undoubtedly dominates the uppermost atmosphere (the thermosphere), but this contains a tiny fraction of the total mass of the atmosphere. Other studies find relationships with geomagnetic activity (caused by electrical currents in the upper atmosphere): for example, Bochníček and Hejda [99] report variations in the North Atlantic Oscillation (NAO) to be more related to geomagnetic activity than sunspots. Thejll et al. [100] also investigated correlations between geomagnetic activity indices and the NAO and found significant correlations in winter for some but not all years. However, solar wind and geomagnetic activity are both highly correlated with OSF which, in turn, is highly correlated with spectral and total solar irradiance (and also correlated with SEP occurrence and anticorrelated with GCR flux). Given that the total masses in the troposphere, stratosphere, and thermosphere are approximately 80%, 19.9%, and 0.1%, respectively, of the total atmospheric mass, any mechanism connecting the solar wind and climate would require a mechanism of truly extraordinary amplification; hence any relationships are most likely to be due to other, correlated, solar outputs.

Paleoclimate Studies

A great many studies have indicated that solar variations had an effect on preindustrial climate throughout the Holocene (the warm interval since the last ice age). These studies have been made in many parts of the world and employ a huge variety of paleoclimate proxies [101–128]. Studies on timescales of up to 1–2 kyr are, in some ways, optimum since such periods are short enough to avoid complications from changes in the geomagnetic field and Earth's orbit [129]. In all cases, the solar change is evaluated from cosmogenic isotopes. The most interesting of these studies employed terrestrial data that are indicators of more than just local climate. For example, Bond et al. [110] studied the average abundance of ice-rafted debris (IRD), as measured in the cores of ocean bed sediment throughout the middle and North Atlantic. IRD are glasses, grains, and crystals that are gouged out by known glaciers, which are then carved off in icebergs and deposited in the sediment when and where the icebergs melt. The sediment is dated using microfossils found at the same level in the core. The abundances of this IRD are sensitive indicators of currents, winds, and temperatures throughout the North Atlantic and reveal high, and highly significant, correlations with both the ^{10}Be and ^{14}C cosmogenic isotopes. A second example has been obtained from the deviation of the oxygen isotope ratio from a reference standard variation, δ^{18}O, as measured in stalagmites in Oman and China in two separate studies [111, 124]. These studies reveal an exceptional correspondence with the cosmogenic isotopes on all time scales between decades and several thousand years. The δ^{18}O is, in each case, a proxy for local rainfall [130] and reveals enhanced precipitation caused by small north–south migrations of the intertropical convergence zone. Large effects are seen because the latitudinal gradients around the sites are large. The fact that the effect is seen at widely spaced locations is evidence for coherent shifts in the latitude of the monsoon belt.

These correlations of paleoclimate indicators are found for both the ^{14}C and ^{10}Be cosmogenic isotopes. The ^{10}Be is a spallation product of galactic cosmic rays hitting atmospheric O, N, and Ar atoms; the ^{14}C is produced by thermal neutrons, generated by cosmic rays, interacting with N. About two thirds of the ^{10}Be is formed in the stratosphere and about one third in the troposphere from where precipitation times into the reservoirs are typically 1 year and 1 week, respectively, and the deposition into any one reservoir is influenced by climate conditions [131–134]. On the other hand, the ^{14}C generated by GCRs takes part in the carbon cycle and is exchanged with the two major reservoirs, the oceans and the biomass. Hence, the transport and deposition into the reservoirs where they are detected (e.g., ancient tree trunks for ^{14}C and ice sheets in the case of ^{10}Be) are vastly different for these two major cosmogenic isotopes. As a result, the possibility that the isotope abundances in their respective reservoirs are similarly influenced by climate during their terrestrial life history can be discounted because the transport and

deposition of each is so different. Thus, it is concluded that the correlations are found for both isotopes because of the one common denominator in their production, namely the incident cosmic ray flux.

One method used to try to understand global climate change from local and regional paleoclimate indicators is "forward prediction of proxies" in which global circulation models (GCMs) are used to simulate the time series of one or more proxies at a number of locations. These modeled time series are then compared to the observed proxy data. In many of these studies, the climate proxies used relate to tropical hydrology and the connections have not yet been fully explained. Shindell et al. [135] used a coupled ocean–atmosphere-composition model, forced by sustained multi-decadal irradiance increases, to show that greater tropical temperatures alter the hydrologic cycle, enhancing the climatological precipitation maxima in the tropics while drying the subtropical regions. The model captures the pattern inferred from paleoclimate records. This may explain drought conditions experienced by the Mayans, Moche, and Ancestral Puebloans civilizations during the late "medieval maximum" (900–1250), and other cultures, which experienced a weakened monsoon during the "Little Ice Age" (c. 1400–1750).

The flux of the GCRs that generate the cosmogenic isotopes is modulated by three influences [129]: (1) the interstellar flux of GCRs incident on the Sun's heliosphere, (2) the GCR shielding by the heliosphere, and (3) the GCR shielding by the Earth's geomagnetic field. The spatial scale of interstellar GCR flux variation in the galaxy is sufficiently large that, compared to distances moved by the solar system through the galaxy, the incident GCR variations on timescales of million years (Myr) and smaller can be neglected. The geomagnetic field shield has varied on timescales of 10 kyr. This variation has, in the main, been gradual during the Holocene [136, 137], although there have been shorter-lived weakenings of the field (which may be geomagnetic reversal onsets that did not develop) such as the Laschamp event around 40 kyr ago [138]. These events complicate the cosmogenic isotope record [139, 140] but are not consistent with the variations seen on timescales of order 1 kyr and less seen, for example by Bond et al. [110], Neff et al. [111], and Wang et al. [124]. This being the case, most of the variations on these timescales arise from heliospheric shielding, i.e., the Sun. To study solar variability effects during the Holocene, several studies have corrected the cosmogenic isotope record to allow for the secular geomagnetic variations [e.g., 90, 93].

With paleoclimate studies, it is important to bear in mind all ten of the potential pitfalls listed in the introduction. An additional problem with the data sequences, which is not a factor for direct observations, is dating [141]. Because record dates are uncertain, "wiggle matching" is often used [142, 143]. Even if this is done with great care, such that the date of any one data point is not moved by more than the accurately computed dating uncertainty, there is inevitably a selection effect at work. This is because the adjustments are made to improve correlations and not to degrade them. For this reason, there is a marked tendency for reported correlations to degrade as the accuracy of the dating is improved.

Observations of Solar Effects in Earth's Atmosphere

This review does not cover the great volume of literature describing and detailing the correlations and connections between solar activity and the ozone concentration, UV heating, and consequent temperatures and dynamics in the stratosphere. Instead, the reader is referred to the recent comprehensive review by Gray et al. (2010) [23]. A later section will discuss mechanisms whereby these stratospheric changes could influence the much larger air mass of the underlying troposphere. This section evaluates the connections between solar variability and the troposphere (on local, regional, and global scales) that have been reported.

A hugely-cited cited paper (cited 405 times in citation analysis using Web of Science, May 2010) by Friis-Christensen and Lassen (1991) [144], reporting a correlation between GMAST and solar cycle length L, highlights several of the problems discussed in the introduction. Firstly, one has to worry about selection effects and the mechanism. Why would L be relevant to climate-effective solar outputs (or was it used only because a correlation was found for L only)? But a more serious problem relates to the data handling and its effects on the significance of the correlation.

Some of the L values in this paper were smoothed using a very long time constant filter. Such smoothing introduces great persistence into the data to the extent that the correlation has no significance [145]. Such correlations can arise, and may even continue for a while, by chance. Lack of significance does not prove the correlation is not present. If it is real it will continue to hold while more data are taken until statistical significance tells us that it has some validity. However, if it is not real it will eventually fail, as was found in this case [146, 147].

As well as persistence of the data series, using a large number of fit variables also reduces the significance of a correlation. This is one issue for multiple regression fits of terrestrial parameters using a combination of one or more solar and other parameters. Scafetta and West (2007) and Scafetta (2009) [66, 148 and a series of previous papers cited therein] (hereafter referred to as SW) propose in their so-called phenomenological methods that multiple time constants are required from which they derived multivariate fits that give up to 65% of the GMAST attributable to TSI change (see Fig. 2). However, SW do not evaluate the significance of the resulting correlations given that they employ a larger number of solar fit variables (the amplitude and time constant of each of the responses). Full understanding needs to also consider the effect of other known external inputs into the climate system (volcanoes, man-made aerosols, greenhouse gasses, land use, etc.) and ensure that fits are not influenced by internal variability and oscillations such as the El Niño Southern Oscillation (ENSO) and the North Atlantic Oscillation (NAO). Many other multivariate fits in this area also fail to test the significance of the best-fit correlation against a well-posed null hypothesis and a properly defined noise model; however, the papers of SW have attracted particular attention because they derive much larger solar contributions to the temperature change. The largest estimates of the solar contribution by SW required use of the ACRIM TSI composite, rather than the PMOD composite, and tests show that both other data and proxies are more consistent with the PMOD composite [35, 41, 62] . This is just one of a number of arbitrary choices made by SW: Benestad and Schmidt (2009) [8] have found that the methodology used in the SW papers is not robust, and sensitivity tests performed on some of SW's choices showed that errors are significantly larger than SW report. They applied the SW procedure to GMAST modeled from known inputs and found that it returned very much larger solar variations than were initially input into the model. As for all multivariate fits, the addition of internal variability and additional forcings greatly confounded the accuracy of the SW procedure. Benestad and Schmidt find that the most likely contribution from solar forcing to GMAST is $7 \pm 1\%$ for the twentieth century and is negligible for warming since 1980 (see Fig. 2). This degree of solar influence is consistent with many modeling and detection–attribution studies (see below) and broadly in line with the computed ratio of solar to anthropogenic radiative forcings: the IPCC report of 2007 assessed that the change in solar radiative forcing over the interval 1750–2005 was in the range 0.06–0.30 W m^{-2} (at the 90% confidence level) with a most likely value of 0.12 W m^{-2} (consistent with the later TSI reconstructions in Fig. 2), whereas the net anthropogenic forcing is in the range 0.6–2.4 W m^{-2} [149, 150]. The TSI change of 1.3 W m^{-2} derived by Krivova et al. [48] for this interval gives a slightly larger radiative forcing of 0.21 W m^{-2}. These forcings should be compared with a total required value to explain the observed GMAST rise, including all feedbacks, of 5.1 Wm^{-2} [41]. The conclusion that global climate early in the twentieth century may show some solar influence, but that in recent decades it has been swamped by anthropogenic effects, is consistent with a great many studies, ranging from correlation studies [7, 8, 151, 152] to detection–attribution studies using GCMs [e.g., 149, 153–157].

The majority of reports of solar signals in global and regional climate are of solar cycle variations and so are subject to the major caveat that these can be easily confused with internal decadal-scale oscillations of the climate system [12, 13, 191]. A statistically significant solar cycle signal throughout the troposphere was reported by Coughlin [293]. Camp and Tung [158] showed significant (and large) differences between mean GMAST for composite surface temperature maps at low and high sunspot activity levels. Such a signal can also be seen in both the ECMWF ERA40 and NCEP/NCAR re-analysis datasets, in which observations have been assimilated with model data [159]. This signal is weaker in the ERA40 set and varies

regionally [160, 161]. Both temperature and mean zonal winds at all heights in the troposphere and stratosphere show significant decadal signal estimated from a multiple regression analysis [162, 163].

A great many studies have reported solar cycle signals in oscillatory modes and features in Earth's troposphere, including: the Northern Annular Mode, NAM [164–166] and the related north Atlantic Oscillation, NAO [167, 168]; the Indian Ocean monsoon [169]; the Southern Annular Mode, SAM [170]; tropical circulation [171–173]; Pacific variability patterns [174–179], in particular, the El Niño Southern Oscillation, ENSO [180, 181]. In addition, observations of temperature variations in the ocean mixing layer are thought to be evidence for resonant responses and "bottom-up" mechanisms [182–185], suggesting a strengthening of the Hadley circulation induced by an increased equator-to-pole temperature gradient.

Regional Climate Effects

Using both a climate model and empirical reconstructions, Shindell et al. [185–187] found that even though solar-induced GMAST changes are small (about 0.3–0.4°C), regional temperature changes associated with solar variability can be quite large. In the model, these occur primarily through a forced shift toward the low index state of the Arctic Oscillation/North Atlantic Oscillation as solar irradiance decreases. This leads to colder temperatures over the Northern Hemisphere continents, especially in winter (1–2°C), in agreement with historical records and proxy data for surface temperatures. Using a stratosphere-resolving GCM, these authors also found that long-term regional changes during the preindustrial period appear to have been dominated by solar forcing [187]. Studies by Mann et al. [188] and Trout et al. [189] have recently supported this idea for the little ice age and medieval maximum, respectively, although other modeling of the medieval maximum suggests that the role of solar changes is not as great as might be expected compared to other factors such as land use [190].

For post-industrial measurements, North and Stevens [191] applied optimal signal detection theory to data from 36 regions around the globe and found the solar signal was small and not highly significant. On the other hand, multivariate fits by Lean and Rind [88] do find strong solar responses in certain regions. Of these regions, this review concentrates on Europe for which the instrumental record is strongest. In this area, as for global responses, the issues of robust procedures and appropriate statistical methods are key considerations. For example, statistically significant signatures of multi-decadal solar activity changes in atmospheric temperatures in Europe have recently been reported by Kossobokov et al. [192] and Le Mouël et al. [193–195], but Yiou et al. [3] and Legras et al. [4] argue that they do not survive proper null-hypothesis testing.

Figure 3 stresses how different the behavior of a regional/seasonal climate in Europe can be from the global or hemispheric mean. The fluctuations for different regions tend to cancel, giving global means that are less variable, more clearly revealing the trends. The plot uses winter means, T_{DJF}, of the Central England Temperatures (CET), which is the world's longest instrumental record and extends back to 1659, at the start of the Maunder minimum. The CET covers a spatial scale of ≈300 km, which makes it a "small regional" climate indicator. In winter, the North Atlantic Oscillation (NAO), and associated changes in thermal advection, contributes to a large fraction of the observed variability of CET [196, 197]. Comparison of parts (a) and (b) shows that T_{DJF} correlates with both open solar flux and the hemispheric mean surface temperature ΔT_{N}. However, the correlation is weak in both cases. Lockwood et al. [198] show that there is a subtle solar influence on winter CET in that it is statistically significant that more cold winters, relative to the hemispheric trend, occur when the open solar flux is low (i.e., when TSI and UV SSI are low and GCR fluxes are high; see Fig. 3c). A number of mechanisms are possible (discussed in the following sections). Early instrumental records from the Maunder minimum indicate an increased frequency of easterly winds influencing the UK temperatures. This has also been deduced from indirect proxies [197], including the spatial patterns of changes in recorded harvest dates [199]. This suggests a link with the incidence of long-lived winter "blocking events" in the eastern Atlantic at low solar activity. Blocking episodes comprise extensive and quasi-stationary anticyclones that can persist for several weeks, leading to extended cold periods in

Solar-Induced Climate Effects. Figure 3

Scatter plots of mean winter Central England Temperature (CET), T_{DJF}, as a function of (**a**) open solar flux, F_S, and (**b**) the hemispheric mean surface temperature anomaly ΔT_N (extended to before 1850 using the median of a basket of proxy reconstructions). Points are colored according to the date using the scale shown in (**a**). The line in (**b**) is the ordinary least squares linear regression fit and the *grey* area bounds the uncertainty range set by the use of proxy reconstructions for ΔT_N prior to 1850. The correlation coefficients for (**a**) and (**b**) are low at 0.23 and 0.25 (significant at the 99.1% and 99.6% levels). In the case of (**b**) this demonstrates the great variability of a regional/seasonal temperature around a global-scale mean. (**c**) is the same as (**a**), for the detrended winter CET data δT_{DJF}, where the detrending allows for the hemispheric change ΔT_N and uses the regression line shown in (**b**). Part (**c**) shows that, even after allowing for the hemispheric trend, most of the coldest winters in central England occur at low solar activity, as quantified by F_S. Lockwood et al. [198] test this against the null hypothesis that F_S has no effect on winter CET values and show that this tendency is statistically significant at around the 95% level

winter as the mild maritime westerly winds are replaced by continental north-easterlies and the land surface cools under cloudless skies. Long-lived Atlantic blocking events at more eastward locations have been found to be more prevalent at sunspot minimum than at higher solar activity, and this leads to colder winters in Europe [200]. This evidence suggests that changes in the occurrence of blocking could be acting to amplify the solar-induced perturbations to the tropospheric jet stream. Other evidence supports this idea. For example, the effects of the changed position and frequency of blocking events may be seen as a manifestation of modes of low-frequency circulation variability that have been found to respond to solar activity, giving increased/decreased frequencies of easterly/westerly circulation patterns over Europe under low solar activity conditions [201, 202]. Winter CET values are known to be strongly modulated by the NAO [196] and modeling has shown that stratospheric trends over recent decades, along with downward links to surface, are indeed strong enough to explain much of the prominent trend in the NAO and hence regional winter climate in Europe between the 1960s and the 1990s [203]. The GCM runs experiments by Rind et al. [204] produce a relative negative phase of the North Atlantic Oscillation/Arctic Oscillation (NAO/AO) during the Maunder Minimum which contributes to the lower European winter temperatures.

Modeling Studies and Detection–Attribution

GCMs have developed rapidly over the last 2 decades, and this has changed the details of the predictions of solar effects. Predicted solar-induced changes in

GMAST have generally been small, even for the larger drifts in solar radiative forcing predicted by the early TSI reconstructions (see Fig. 1). Full comparisons are complex because the TSI reconstructions have evolved at the same time as have the complexity and resolution of the models. As expected, weaker solar effects are found for the smaller TSI drift predicted by the more recent reconstructions: for example, compare the results and inputs of Wigley and Raper [24], Zorita et al. [205], and Stendel et al. [206]. Examples of recent GCM experiments giving a relatively large bottom-up solar effect have been presented by Rind et al. [207]. The input solar forcing change between the Maunder minimum and the present day used was 0.68 W m^{-2} (with an input of 1.9 W m^{-2} from anthropogenic forcing change). This solar forcing is relatively large, compared with the range 0.06–0.30 W m^{-2} quoted by Hergel et al. [149] and Solomon et al. [150], and the experiments generally gave a large solar contribution (near 30%) to the total GMAST rise (the total rise being larger than observed). The tropical response, in particular, was much greater than observed, consistent with the excessive TSI change input to the experiments.

Rind et al. [207] used a model with a coupled stratosphere at four different resolutions to investigate various aspects of top-down solar cycle influence on the troposphere/stratosphere system. The results show that the stratospheric response is highly repeatable and significant. Stratospheric westerly wind increases were found to extend down into the troposphere and in some experiments the jet stream weakened and moved poleward. The predominant tropospheric response consisted of a warming of the troposphere, with coherent changes in regional precipitation. The tropospheric response was often not great, but was similar in all the different simulations. All runs revealed both top-down and bottom-up solar effects but they account for only a small percentage of the total GMAST variance. A model described by Meehl et al. [174–176] includes ocean–atmosphere coupling and a stratosphere, and so can include both top-down and bottom-up solar forcing. This model suggests potential resonant connections between solar forcing and the ENSO oscillation.

Model predictions are a key part of "detection–attribution" studies, in which the effect of varying an input to the GCM must be detected above the internal variability of the climate system modeled by the GCM. Results do depend on which GCM is used, although there is also a considerable degree of agreement between the different models. In many studies, the input forcings are multiplied by variable amplification "β" factors to get the best fit to the variation of the global spatial pattern of surface temperature. For example, studies by Stott et al. [153] found that for solar forcing $\beta = 3$ was required, but this unexplained amplification of the solar radiative forcing may have been overestimated because of the characteristics of the GCM used (see review by Ingram [157]) and/or because of instrumental problems with the data sequence [209]. A comprehensive review of detection–attribution methods and results has been given by Hegerl et al. [210].

Stratosphere –Troposphere Coupling and Top-Down Solar Forcing of Climate

Dynamical coupling across the tropopause [211] means that stratospheric forcing can influence the underlying troposphere [e.g., 212–214], and under some circumstances, robust tropospheric responses are indeed predicted by the models. Observational studies show that stratospheric perturbations (e.g., stratospheric warmings) typically last for at least a month and on average affect the troposphere within approximately 2 weeks [208, 215]. Tropospheric jet streams have been shown to be sensitive to the solar forcing of stratospheric temperatures [18, 19, 216, 217]. This could occur through disturbances to the stratospheric polar vortex [218], which can propagate downward to affect the tropospheric jets [219–221], or through the effects of tropical stratospheric temperature changes on the refraction of tropospheric eddies [222, 223]. Models [e.g., 187] predict that perturbations can descend from the stratosphere to the surface by altering the propagation of planetary waves coming up from the surface – an effect that has been observed in data [224]. However, models that do not yield realistic stratospheric dynamics fail to capture these wave flux changes. The tropospheric response is reduced when planetary waves are suppressed in the stratosphere by additional damping or when the strength of

the stratospheric jet is increased. The models show that the stratosphere could play a crucial role in recent trends. For example, Scaife et al. [203] have demonstrated that stratospheric trends over recent decades, along with downward links to surface, are indeed strong enough to explain much of the prominent trend in the NAO and hence regional winter climate in Europe between the 1960s and the 1990s. Such effects are not just found in the northern hemisphere [225].

A wide variety of tropospheric responses have been suggested [e.g., 226–229]. A predicted effect on tropospheric jet stream latitude is that increased heating of the equatorial stratosphere causes a slight poleward motion, an effect that has been reproduced in simple GCM simulations [230], deduced from other data [231], and has been suggested as a cause of equatorial precipitation changes in the little ice age [232].

The solar influence on winter European temperatures, discussed in the section above, suggests that the occurrence of the blocking phenomenon could be acting to amplify the solar-induced perturbations to the tropospheric jet stream [233]. Solar cycle control of the location, strength, and occurrence of blocking events has been detected by Barriopedro et al. [200] and Woollings et al. [295].

Cosmic Ray Modulation of Clouds

A long-standing suggestion is that cosmic rays can aid the formation of clouds (see reviews by Carslaw et al. [234] and Kirkby, [235]). This would be a highly significant effect because clouds modulate Earth's energy balance by (1) changing Earth's albedo, A, and (2) by enhancing the IR greenhouse trapping effect. The balance between these two competing effects is dependent on the cloud altitude: for low clouds the albedo effect dominates whereas the lower temperature of higher altitude clouds means that the greenhouse trapping dominates. Variations in Earth's albedo are particularly poorly known [236, 237]. A great many papers have been written about low-altitude global cloud cover arguing that it shows a statistically significant solar cycle variation, consistent with GCR modulation of the growth of cloud condensation nuclei [238–242]. Other studies find no significant effect [243–248]. A third set of studies finds significant correlations but only in restricted regions [249, 250], whereas a fourth set reports a solar cycle variation but finds it to be more consistent with solar UV irradiance variability [249, 251, 252]. Voiculescu et al. [253] argue that both UV and GCRs have an effect. Harrison [254] detected a 1.68-year oscillation in the long diffuse fraction data series from the Lerwick (maritime) station – an oscillation found in the open solar flux and GCR fluxes but not in the SSI or TSI variations [86], hence supporting a direct effect of GCRs. It is expected that the effect would be more significant in clean maritime air where there is a shortage of CCNs for water vapor to condense on, and thus air ions generated by GCRs may be a more significant factor in maritime regions [255, 256].

The arguments against such direct cosmic ray-cloud connection have been: (1) given the atmospheric supersaturations, there is no established mechanism that can cause the effect; (2) the intercalibrations involved in the composite cloud cover dataset used render it unsuitable for this type of long-term variability analysis [e.g., 257]; (3) the data sequences are too short and so the significance of the correlations is low or marginal (For example, Sun and Bradley [246] show that the uniquely high cosmic ray-cloud cover correlation in the period 1983–1999 over the Atlantic Ocean, is greatly weakened when an extended data set is used); (4) Periods of low geomagnetic field, particularly the Laschamp event, gave enhanced GCR fluxes in the Earth's atmosphere but did not influence climate in the Greenland area [20]. Of these objections, only argument (4) suggests that such a mechanism is not effective, whereas arguments (1–3) all indicate that the evidence in its favor is inadequate (but cannot be used to argue that it is not active). In relation to (4), there is some evidence that the failure to see an effect of the Laschamp event [258] may have been a local characteristic of the climate in the Greenland area [116]. Other studies give indications of an influence of the geomagnetic field on preindustrial climate. Recent reports of associations between the main geomagnetic field and climatic changes [259–263] would be very significant, if confirmed. These changes have also been linked to latitudinal motions of the intertropical convergence zone [259, 264] and effects on civilizations

that had a critical dependence on rainfall [260, 264–267]. Nevertheless, objection (4) remains a key debate.

Harrison and Stephenson [268] found evidence for a GCR effect on diffuse fraction measurements at a variety of UK meteorological stations. As these are homogeneous sequences of simple measurements, this does counter objection (2) to some extent; however, the effect was small and no allowance is made for the effect of the variable aerosol optical depth. The best chance of answering objection (1) is the CLOUD experiment at CERN [269], which has just begun to studying the "ion-aerosol clear-air" mechanism. However, Pierce and Adams [270] have estimated that this mechanism is two orders of magnitude too small to explain the reported effects. Other mechanisms involving the atmospheric electric field [271] have been proposed [272–275].

In addition to the solar cycle variation in GCRs, there are sudden decreases in GCR fluxes (Forbush decreases) and these have been reported as giving responses in ground-based cloud data [276] and in satellite cloud cover data [277] using "compositing" analysis (also called "superposed epoch" and "Chree" analysis). The problem with these studies (particularly if the satellite dataset are employed) is that there are very few large Forbush decreases and the results appear to be dominated by one or two very large events and other studies have failed to find this response [296]. The delay of the putative effect is also a puzzle. Nevertheless, it has been independently reported that 3% of cloud variability on short timescales may be associated with GCRs [278]. The potential importance of this effect is that there are long-term changes in the open solar flux [11] that yield the long-term changes in GCRs [91–93], which could in turn introduce long-term changes in climate if the mechanism is sufficiently effective [94].

Solar Energetic Particles and Ozone

SEPs are directed toward Earth poles by the geomagnetic field where they generate nitrates on hitting Earth's atmosphere as demonstrated, for example, in observations by Mlynczak et al. [279]. These nitrates are seen to migrate downward over time [280, 281], resulting in catalytic destruction of stratospheric ozone [282]. Large SEP events generate considerable transient polar ozone depletions, which persist in winter until UV irradiance of the polar stratosphere resumes [283–286]. Recently, Seppälä et al. [287] reported changes in polar winter surface temperatures, which they associate with large SEP events, based on the modeling predictions of such effects by Rozanov et al. [288].

Are the GMAST Data Correct?

There are difficulties in combining the available data into a single homogeneous GMAST anomaly time series. Different approaches are taken and different data used. An example is the way that regions of missing data are handled varies – GISS [64] interpolates into areas of missing data, whereas HadCRUT3v [65] does not. Nevertheless, as shown in Fig. 2, the GISS and HadCRUT3v reconstructions agree rather well and both show a recent plateau in GMAST anomaly, such that the HadCRUT3v value is still below the 1998 level although this is not true of GISS.

There are, however, potential issues that could influence both reconstructions. For example, Thompson et al. [209] report that sea surface temperature measurement biases may have contributed a downward step in the GMAST of about 0.3°C in the middle of the twentieth century. Correcting this would probably improve the agreement in Fig. 2 with the GCM model fit shown, but initial indications are that this correction would also lead to a lower solar contribution being derived by detection–attribution studies. In other words, if Thompson et al. are correct, the amplification of the solar forcing (with a beta factor >1) in some detection–attribution studies would be an example of data "snooping" because it relied on an artifact in the data.

Lockwood [7] carried out a simple multivariate fit analysis that fits the plateau in the HadCRUT3v GMAST well. In this fit, the plateau arises mainly because of the lack of El-Niño events since the major 1998 event, with a small contribution from the solar decline. This fit demonstrates that this feature could be readily explained as the combined effect of known influences. (Note that this statement can be no more definitive than this because of the limitations inherent in the multivariate fits, as discussed earlier.) The plateau is also nothing unusual, compared to past variations around the upward trend [41, 289, 290]. The same is true for the corresponding plateau

(or even slight fall) in global mean ocean surface layer temperature [297].

Future Directions

From solar-induced variations of cosmogenic isotopes over the past 10^4 years, Lockwood [67] has deduced there is an 8% chance that the Sun will return to Maunder minimum conditions within 50 years. Feulner and Rahmstorf [291] used a coupled model to predict that this will offset anthropogenically rising global mean temperatures by no more than 0.3°C in the year 2100, relative to what would happen if the solar output remained constant. Similarly Lean and Rind [292] found that the solar decline would delay reaching a given temperature level by no more than a decade. Thus these predictions show that continued solar decline will do little to alleviate global warming. However, the decline will do much to end the debate about the fraction of global warming that can be attributed to solar change. For the first time since anthropogenic climate change became rapid, solar and anthropogenic trends are now in opposite directions. Non-robust fits (of low statistical significance, suffering from data snooping and selection effects, and which have not isolated internal variability) will fail sooner rather than later because of the change in solar behavior. Thus the next few years will provide much better estimates of the solar contribution. Concerning the global temperature rise, there is every indication that these new estimates will, if anything, be smaller than previous estimates. On the other hand, there are indications that some regional climates are much more susceptible to solar changes than others. Understanding and differentiating "top-down" and "bottom-up" solar forcings will be key because these will have very different effects on the spatial patterns of the responses. Key advances in this area will be made in modeling, with higher resolution in time and space, better understanding of numerical noise and of the relationship of natural climate variability to that in the model behavior, fewer parameterizations, better definition of the inputs forcings, and inclusion of more biological responses alongside the physical and chemical. However, these developments will take time and in many cases mitigation and adaptation decisions may have to be taken based on the most successful of the current model simulations.

Glossary

Woody fuels Biomass from trees, bushes, and shrubs.

Herbaceous fuels Biomass from plants that have a non-woody stem and which die back at the end of the growing season.

Pellets Densified biofuel made from pulverized biomass with or without additives usually with a cylindrical form, random length typically 5–40 mm, and broken ends. Max diameter: 25 mm.

Physical-mechanical properties Fuel characteristics such as surface properties, geometry, size and size distribution, fine matter content, flowing and bridging properties, resistance to abrasion, bulk, and particle density.

Biomass ash Solid mineral residue obtained from complete fuel combustion.

Energy density Ratio of net energy content and bulk volume.

Definition of the Subject

In the context of the future energy supply and renewable energies biomass is an energy source with a high potential and it has raised many expectations in society and politics. This high interest is also caused by the huge variety of possible resources and the many technical options of application for heating, electricity production, or mobility. The physical appearance of biofuels is also quite variable: biomass can be provided as solid, liquid, or gaseous fuel determining different technological conversion paths.

However, the overview presented here is limited to solid biomass resources. The paper aims at understanding the specialties of natural solid biomass fuels, which are directly used for thermochemical conversion mainly by an end user who has the goal to produce heat and/or electricity. Therefore, raw materials for biological conversion (e.g., fermentation for biogas production) are not characterized. This is also true for those resources that are relevant for non-thermochemical upgrading processes as applied for the production of liquid biofuels (e.g., physical extraction or ethanol fermentation).

Any biomass-containing waste streams are also not considered here, even if they are used for energetic purposes. The goal is rather to define, present and discuss the properties of the main natural untreated solid biomass fuels, which are either residues or field crops, and to indicate the consequences for the conversion process.

Introduction

The provision of solid biofuels that meet high quality standards is becoming increasingly important in order to fulfill the rising technical and environmental requirements for their utilization. The process of a thermochemical conversion is largely influenced by the fuel properties, and this applies to the pollutant formation. Therefore, the specific characteristics of the respective fuels have to be adequately regarded. It is also essential to understand their impact in the conversion process in order to assess their importance and to evaluate chances for improvements. This is a major goal of the here presented study.

The avoidance of unfavorable fuel properties can only be considered if the reasons for any excessive fuel related phenomenons are known and can be explained. It is therefore important to analyze the production chain and to identify the key impacts for fuel quality.

In general, quality-determining factors of biomass fuels can be attributed to two major phases of the life cycle: the growing phase, in which mainly the compositional characteristics are developed, and the supply

phase, in which mostly the physical-mechanical parameters determined (Fig. 1). Only some of the quality influencing factors identified during these phases have been studied and can be quantified at least to some extend with regard to their effectiveness [27].

In view of the influences and the history of the fuel provision as outlined in Fig. 1, the selection and specification of the suitable fuel for a given process is thus an essential part of the optimization strategy of an energy use concept for biomass. Both, the direct determination of the critical quality parameters as well as the fuel assessment by knowing the species and the influences along the provision chain can lead to a sound assessment of the fuels applicability.

Fuel Characterization Schemes and Overview

Fuel specification can either be done directly, by determining the relevant fuel parameters, or indirectly, by retracing the fuel to the origin and/or to the actual species which allows fuel assessment through experience. Both approaches are discussed in the following.

Characterization by Determining Specific Fuel Properties

For the energetic use, three groups of characteristics are decisive: the elementary composition, the technical combustion properties, and the physical-mechanical properties (Table 1). Sometimes the last two groups are also compiled as "physical parameters." Most of the parameters allocated to the three groups are quality-relevant parameters, because they can influence the thermochemical and the pollutant formation processes or they are determining the usability of the produced ash or slag residues.

Below therefore the significance of each of the presented fuel parameter is discussed individually. This applies to the characteristics as listed in Table 1, which can serve as an overview of important fuel properties. For better understanding of the thermochemical conversion processes (i.e., pyrolytic decomposition, gasification and oxidation) the main macromolecular constituents of lignocellulose biomass fuels are also presented in the following.

Characterization by Origin

Many of the measurable fuel parameters and their usual variation are already determined by the fuel origin, which is described either by the species or raw material type or by the processes for harvesting and treatment. The description and the retracing of fuels to their origin is therefore an essential element of an effective quality assurance management for solid biofuels. Therefore,

Solid Biofuels, Fuels and Their Characteristics. Figure 1
Factors influencing the quality of solid biofuels ([27], modified)

Solid Biofuels, Fuels and Their Characteristics. Table 1 Quality relevant characteristics of biomass fuels and their impact in the utilization chain

Quality parameter	Main impact
Element concentration	
Carbon (C)	Calorific value, oxygen demand, particle emissions
Hydrogen (H)	Calorific value, oxygen demand
Oxygen (O)	Calorific value, oxygen demand
Nitrogen (N)	NO_x- and N_2O-emission
Potassium (K)	Ash softening behavior, high temperature corrosion, particle emission
Magnesium (Mg)	Ash softening behavior, ash embedding of pollutants, ash utilization, particle emission
Calcium (Ca)	Ash softening behavior, ash embedding of pollutants, ash utilization, particle emission
Sulfur (S)	SO_x-emissions, high temperature corrosion, particle emission
Chlorine (Cl)	Emissions of HCl and halogen-organic compounds (e.g., PCDD/F), high temperature chlorine corrosion, particle emission
Heavy metals	Ash utilization, heavy metal emissions, catalytic impacts (e.g., in PCDD/F-formation), particle emission
Technical combustion properties	
Moisture content	Calorific value, storability (losses by biodegradation, self ignition), fuel weight, combustion temperature
Calorific value	Energy content of fuel, dimensioning of combustion plant
Ash content	Particle emission, residue management and utilization
Ash melting behavior	Slag formation and deposits, operational safety and -continuity, maintenance requirements
Physical-mechanical properties	
Shape and dimensions	Allocation to mechanical systems and furnace types, bridging properties, ignitability, drying speed
Size classification/Fine matter content	Clogging in conveyors, flowability and bridging properties, aeration and drying properties, dust formation, risk of explosion
Bridging properties	Flowability, failures during transhipment and storage extraction
Bulk density	Storage and transport efforts, power requirement of conveyor motors, volume of storage
Particle density	Bulk density, pneumatic conveying properties, combustion properties (specific heat conductivity, etc.)
Resistance to abrasion	Amount of fines (dust formation, demixing)

a uniform identification system was elaborated in the course of the European standardization process for solid biofuels [18]. In this system, the possible features of origin and/or the biomass fractions are comprehensively defined following a hierarchical classification and enumeration scheme. It allows characterizing the given fuel with variable levels of detail, depending on the knowledge about the fuel. This is done by distinguishing four major groups [18]:

- Woody biomass (digit 1)
- Herbaceous biomass (digit 2)
- Fruit biomass (digit 3)
- Blends and mixtures (digit 4)

Theses major groups are divided into several other groups and subgroups. As an example, Figs. 2 and 3 show the classification for the two largest groups, the woody and herbaceous fuels. The given labeling numbers allow a simple reference to specific fuels or fuel groups (e.g., to be used in directives, contracts, or fuel quality standards).

Also the third major group (fruit biomass) is divided into several subclasses. Here a differentiation between orchard and horticulture fruits, by-products and residues from fruit processing industry, as well as blends and mixtures is made. Both subgroups have further subdivisions [18].

The term "blends and mixtures" not only used for the fourth major group but also for several sub-groups is addressing raw materials of variable origin within the given group in the classification scheme and it appears on all four levels. Blends are defined as intentionally mixed biomass, whereas mixtures are unintentionally mixed biomass. A mixture between chemically treated and untreated material is to be classified as a chemically treated fuel [18].

Fuel Composition

Molecular Composition

Biomass fuels are consisting of the three biopolymers cellulose, hemicellulose, and lignin. They usually provide more than 95% of the plants dry matter. As further groups of components, the extractives (e.g., fat and resin) and the ash need to be mentioned. Annually harvested crops can also contain a significant amount of protein. The share of masses for these main constituents in wood and herbaceous fuels is given in Table 2.

Among all organic substances, the cellulose is most widespread in nature. Cellulose forms the structural

substance of the cell wall and it is responsible for the tensile strength of biomass. Cellulose consists almost fully of congenerous D-glycoside molecules which are linked via a ß-(1–4)-binding to form an unbranched polysaccharide (Fig. 4). The degree of polymerization or the length of the chain can vary widely. Depending on the wood species it can reach up to 14,000 molecules [47].

The term hemicellulose (also polyose) specifies a second important group of biopolymers. Hemicellulose is a branched polysaccharide formed by various monomeric units. Their function in the plant is manifold. They serve as structural element in the cell membrane, as reserve material, or they act cell wall cementating through their adhesive properties. Hemicellulose in detail is either hexose (glucose, mannose and galactose), pentose (arabinose, xylose), desoxyhexose, or one of various hexuronic acids.

The actual filling material of lignocellulose materials is lignin. It does not appear as independent material but it is always a companion of the cellulose. Due to its cementation properties it is responsible for the pressure resistance of wood. Lignin is a three dimensionally linked aromatic polymer compound with alcyl-benzol-structure. It consists of variously bound phenylpropane units substituted by hydroxyl and methoxyl groups (Fig. 5). A strong lignification ensures that the sprout of the plant can remain in the upright position when the water pressure (turgor) usually responsible for stability of less lignified plants becomes weak. Therefore, strongly lignified materials (e.g., wood) have relatively low moisture content. Wood fuels have a lignin content of 20–30%, while for annually harvested plants it is usually below 20% (Table 2).

In lignin the carbon content is significantly higher (64%) than for cellulose (42%). Differences in the

Solid Biofuels, Fuels and Their Characteristics. Table 2 Share of cellulose, hemicellulose, lignin, and other components in various biomass fuels ([24, 41, 40]; no specification is made concerning the deviation to 100% mass; *na* not available)

macromolecular composition are therefore directly influencing the total carbon content as the main determinant for the calorific value of the dry matter. High contents of lignin and extractives are therefore raising the calorific value (section "Calorific Value").

Elemental Composition

Plant biomass is composed of many elements, of which 26 are known to be essential for growth. They can be distinguished between main elements and trace elements.

The main elements are carbon (C), oxygen (O), and hydrogen (H), which arise from the CO_2-assimilation and the H_2O-uptake, and the six major nutrients nitrogen (N), potassium (K), phosphorus (P), calcium (Ca), magnesium (Mg), and sulfur (S), as well as the also relatively prevalent chlorine (Cl), which does not count as a nutrient. These elements are either decisively contributing to biomass formation or they play an important role as associated material in plant nutrition.

Apart from these elements the plant mass also contains trace elements such as silicon (Si), sodium (Na),

Solid Biofuels, Fuels and Their Characteristics. Figure 5
Chemical structure of beech wood lignin [45]

iron (Fe), manganese (Mn), zinc (Zn), copper (Cu), molybdenum (Mo), cobalt (Co), lead (Pb), aluminum (Al), chrome (Cr), cadmium (Cd), nickel (Ni), mercury (Hg) or arsenic (As). Several of them are listed as essential micro nutrients while others can be harmful to plant life. The usual concentrations of these elements and their impact on in thermochemical conversion are discussed below.

Main Elements *Carbon, oxygen, hydrogen.* Solid biomass consists mainly of carbon (C), oxygen (O), and hydrogen (H). The component that most determines the release of heat via oxidation is the carbon. Hydrogen also provides energy by oxidations while oxygen supports these reactions. Woody fuels contain the highest carbon content among the biomass materials (about 47–50 mass-% in dry matter). Non-woody biomass fuels have a carbon content of 43–48%. Their oxygen content is between 40% and 45% (dry basis) and for hydrogen the content is between 5% and 7% (see Table 3).

From these data the molecular formula for wood is around $CH_{1.44}O_{0.66}$. Significantly, higher carbon contents are given for biomass with high oil content (e.g., rapeseeds). A higher share of non-burning constituents (ash) can cause lower carbon content. This, for example, applies to roadside woodcuttings with usually have a higher ash content.

Opposite to coal (e.g., hard coal, brown coal), which are an outcome of a natural carbonization process, the carbon in solid biofuels is prevailing in a partly oxidized mode with a respectively higher oxygen content, thus having a lower carbon concentration. This explains the lower caloric value compared to fossil coal (Table 6).

Nitrogen. The nitrogen(N)-content varies significantly between different biomass types. This variation reflects the differences in composition of solid biomass. High protein containing plants or plant fractions are always higher in nitrogen content than typical lignocellulose materials as wood or straw. This applies mainly to the generative parts of crops like grain, oil

Solid Biofuels, Fuels and Their Characteristics. Table 3 Contents of main elements in untreated natural biomass fuels compared to hard and brown coal (mean values according to [31], for coal: [56])

seeds, and protein plants, but it is also true for herbaceous crops, which have a high value as animal feed. Correspondingly, the nitrogen content is relatively high for grain kernels, whole grain plants and animal feed grass. Spruce wood contains only little nitrogen of around 0.1–0.2% (1,000–2,000 mg/kg) in the dry matter, while grain straw ranges in the order of 0.5% (Table 3). Also slightly increased nitrogen contents are observed for short rotation coppice; this is explained by the higher content of bark in the total wood mass.

The variations within a specific biomass assortment are usually relatively low for wood. This is demonstrated by the frequency distribution of certain

concentration classes (Fig. 7). Concentrations of above 0.6% or below 0.3% are, for example, quite rare in wood fuels. Higher values and variation are given for straw from rapeseed, maize, sunflower, or hemp crops. The higher variation of nitrogen concentrations in herbaceous fuels is mainly due to differences in fertilization (e.g., different fertilization level or fertilization timing).

The nitrogen content of the fuel is directly affecting the formation of nitrogen oxides (NO_x) because this element is usually completely released into the volatile phase during combustion or gasification. The oxidation of the chemically bound nitrogen in the fuel is by far the most relevant formation path for NO_x. Therefore, the NO_x formation is usually declining with lower N-content in the fuel. Nitrogen embedding into the ash hardly happens. Nitrogen can also be responsible for the formation of N_2O (laughing gas) which is harmful to the climate.

Potassium. Similar to nitrogen there are also major differences in the potassium (K)-content between periodically fertilized field crops and perennial wood cultures usually not fertilized (e.g., forest or short rotation coppice). However, the potassium is – other than for nitrogen – not mostly prevalent in the generative parts of the plants, but it occurs mainly in the sprout and leaves. Therefore the potassium content of grain kernels is low (ca. 0.5–0.7% or 5,000–7,000 mg/kg, dry basis) while grain straw usually has K-concentrations around or above 1% (Table 3). Wood fuels however show potassium contents of hardly higher than 0.35% and their variation is low. This is not the case for grain straw, where the concentration varies between 0.2% and 2.5%. This larger bandwidth is not only a result of variable fertilization levels. It can be caused by differences in leaching by precipitation during the phase between ripening and harvest [31, 53].

Potassium is involved in the corrosion process on heat exchangers or on flue gas conducting parts of a furnace. The participation of potassium (and sodium) in corrosion is based on the fact that these elements can form gaseous alkali chlorides which condense and deposit on heat exchanger surfaces or on fine particles during cooling. These deposits can react with sulfur dioxide (SO_2) from the flue gas on heat exchanger surfaces and form alkali sulfates and elementary chlorine (Cl_2). The latter can diffuse though the porous cinder layers toward the tube surface of the heat exchanger where it is reduced to iron chloride ($FeCl_2$) due to the prevailing reductive conditions. Under the large temperature differences within the layer of deposits on the heat exchanger the partial pressure of $FeCl_2$ is differing largely. This allows the $FeCl_2$ gaseous under the prevailing conditions to diffuse away from the tube surface where they again undergo oxidizing conditions. The iron is thus oxidized again and a part of the released chlorine is repeatedly available for the corrosion process (so-called high temperature chlorine corrosion, Fig. 6) [48].

In the oxide state, potassium becomes volatile during combustion and only after cooling in the course of the flue gas tract it is condensed as fine particle. Therefore, potassium is listed among the aerosol forming elements of biofuel components [3]; this property can cause significant increases of particle emissions [35].

Potassium also influences the ash softening properties of a biofuel as it lowers the melting temperature of the ash (section "Ash Melting Properties"). The largest share of the potassium is thus embedded into the solid ash residues.

Calcium, magnesium, phosphorus. Biomass contains calcium (Ca), magnesium (Mg), and phosphorus (P). The calcium content ranges between 0.3% and 1% (for bark even higher), but in herbaceous fuels it can be significantly higher. The calcium content is low in grain straw and kernels. But it can be high in straw from other crops (e.g., rapeseed straw, sunflower straw) (Table 3).

In the combustion process, calcium improves the ash softening behavior by increasing the melting temperature of the ash (section "Ash Melting Properties"). For several fuels with an unfavorable ash-melting behavior, it can therefore be useful to mix calcium-containing additives (e.g., lime) to the fuel in order to raise the ash melting point [57]. High contents of alkaline earth elements (mainly Ca) can also lead to a higher embedding of sulfur into the ash, thus preventing the sulfur to be released as harmful SO_2 via the flue gas.

The manganese(Mg)-content in wood fuels is relatively low (ca. 0.04–0.1%). This is also true for phosphorus which is usually found in concentrations of <0.1% (for wood) or about 0.2% (herbaceous fuels) (Table 3). The three elements calcium, magnesium, and phosphorus increase the fertilization value of the ash.

Solid Biofuels, Fuels and Their Characteristics. Figure 6
Mechanism of high temperature chlorine corrosion at a heat exchanger surface [48]

Sulfur. The sulfur(S)-content in biomass fuels is strongly depending on the given macromolecular composition. For some amino acids and enzymes sulfur is required as an essential crop nutrient, but mostly only low quantities have to be provided by fertilization. However, the sulfur supply is usually significantly higher for field crops than for unfertilised woodland or for hardly fertilized short rotation coppice. Rapeseed straw has an average sulfur content of 0.3% in the dry matter. This is the highest among the biomass fuels. For wood fuels a sulfur content in the range of 0.02–0.05% can be expected and for grain straw the S-content is usually below 0.1% (Table 3). In general biomass fuels are low sulfur containing fuels.

In a complete thermochemical conversion, the sulfur oxide emissions are mainly determined by the sulfur content in the applied fuel. Sulfur is mostly changing into the gaseous phase by forming SO_2, SO_3, and alkali sulfates [48]. Similar to chloride, sulfur compounds can also condense during the cooling phase of the flue gas while forming alkaline or alkaline earth sulfates which are deposited either on heat exchanger surfaces or on other flue gas particles. A large portion of the sulfur content in the fuel (ca. 40–90%) is embedded into the ash, depending on the degree of particle separation by the applied flue gas purification system.

Sulfur can also indirectly contribute to increased corrosion (e.g., on heat exchanger surfaces). This can occur at higher SO_2-concentrations in the flue gas. Due to an increased sulfate binding in the prevailing alkaline and alkaline earth chloride compounds a release of corrosive chlorine (Cl_2) is supported [48].

Under certain circumstances, sulfur can also play a role in preventing the formation of dioxin and furan (PCDD/F). This can happen by changing and inactivating the catalytically acting copper oxides. In coal combustion, for example, a PCDD/F inhibiting effect is observed when the Cl/S-ratio in the fuel falls below 1.0. The chlorination or aromatics during PCDD/F-formation is usually even fully prevented at a Cl/S-ratio below 0.1 [25, 56].

Chlorine. Chlorine (Cl) is a major associated material in potassium fertilizers [31]. Therefore its content in herbaceous biomass fuels is significantly higher than in wood fuels. This is because in forest operations and in short rotation forestry practice fertilization does usually not happen.

Consequently wood fuels show very low chlorine contents of about 0.005–0.02% in the dry matter. Often these contents are even below the detection limits of the applied methods. But for grain straw the chlorine content is several times higher (ca. 0.2–0.5%) and in coastal areas even concentrations of more than 1% are possible. Very high Cl-content is often observed in straw from rapeseed and sunflower (ca. 0.5–0.8%). This is also true for conventional hay (e.g., from ryegrass) (Table 3).

For the chlorine content, the bandwidth of variation is relatively high. In non-wood crops [31] this variation is on the one hand caused by the variable chlorine freight transported onto the land by fertilization and on the other hand it is influenced by leaching from the soil or from the died-off crop through precipitation. Such leaching from the crop can account for 60–80% chlorine reduction in the fuel [31, 53]. Therefore the leached "gray" straw is – from the viewpoint of combustion – always preferable compared to any fresh "yellow" straw. Both straw qualities are usually available in a region or during a harvesting season, thus the frequency distribution curve for the chlorine concentrations follows a pattern with a peak on the left side (Fig. 7).

The significance of chlorine in a thermochemical conversion process is manifold. For example, Chlorine is participating in the formation of hydrogen chloride (HCl) and dioxin/furan (PCDD/F) [38, 39, 48]. In spite of a high chlorine embedding into the ash between 40% and 95% [48], the HCl emissions via flue gas can be critical for certain Cl-rich fuels (e.g., grain straw) which then require secondary flue gas treatment. Furthermore, chlorine is acting corrosive at the surface of heat exchangers. This happens in interaction with alkaline and alkaline earth metals and with sulfur dioxide (SO_2). Additionally, chlorine is known to be an aerosol forming element [3], which can contribute to increasing particulate matter emissions during combustion [35].

Trace Elements All remaining elements are defined as trace elements. They are mostly heavy metals. These elements mainly determine the quality and usability of

Solid Biofuels, Fuels and Their Characteristics. Figure 7
Frequency distribution of values for selected fuel parameters measured in spruce wood and grain straw (*n* number of data) [31]

the ash accumulated during combustion or gasification. The easy volatile heavy metals cadmium (Cd), lead (Pb), and zinc (Zn) are listed as major aerosol forming elements increasing the emissions of particulate matter during combustion [3].

Opposite to the main elements, the variation of the trace element content is largely higher and less predictable. But some general trends and differences between the untreated natural fuels can be identified. Wood fuels from the forests, for example, are usually higher in heavy metal content than annually harvested crops. Particularly the bark from spruce wood takes here a top position for most heavy metals (for As, Cd, Co, Fe, Hg, Mn, Mo, Ni, and Zn). For the other wood fuels a differentiation has to be made between the long-term growing forest trees and the short rotation coppice (e.g., poplar, willow), where forest wood has almost consistently higher heavy metal contents. This is primarily due to the long rotation time where the forest trees are exposed to heavy metal depositions from the atmosphere. A second explanation is given by the fact that the pH-value of forest soils are usually low, which leads to a higher heavy metal solubility and thus to an increased element uptake via the roots.

An exception is here given for cadmium, which is relatively high in young willow trees due to a specific capturing ability which is given for this crop. Therefore, willow can be used for melioration of cadmium polluted fields [31, 54]. Apart from cadmium, the content of nickel, chrome, and mainly mercury, lead, and molybdenum is usually quite low for short rotation coppice.

The heavy metal content represents an important characteristic for the differentiation between naturally untreated and treated or used fuels. Increased heavy metal contents are often observed for grass cuttings or wood from roadsides [31]. Therefore some heavy metals are used as lead indicators for any nonnatural or untreated background. For example, a rapid test was developed for zinc (combined with the element chlorine) which is determined in the accumulated ash of a furnace in order to find evidence for illegal fuel use [46].

Also for compressed biomass such as briquettes the proof for using only natural untreated raw material can be provided by meeting the limitations of a fuel standard. For example, in Germany the requirements for wood briquettes concerning heavy metals were fixed according to the standard DIN 51 731 [8]. It requires staying below the following threshold values:

- Arsenic (As) < 0.8 mg/kg
- Cadmium (Cd) < 0.5 mg/kg
- Chrome (Cr) < 8 mg/kg
- Copper (Cu) < 5 mg/kg
- Mercury (Hg) < 0.05 mg/kg
- Lead (Pb) < 10 mg/kg
- Zinc (Zn) < 100 mg/kg

Heavy metals can primarily influence the ash quality, as they largely remain in the combustion residues and can limit their reuse for fertilization purposes. But, the heavy metal concentrations of different ash fractions from a thermochemical process can largely differ. Cadmium, zinc and lead are easier volatilized than other heavy metals. In the flue gas they are thus condensed on fly ash particles during the cooling phase and therefore they are accumulated in these particles (e.g., fabric filters, electrostatic precipitators). By separating the bed ashes from the cyclone or filter ashes for reuse or disposal the pollution risks by fertilization can be controlled and minimized [48].

Some heavy metals can act catalytically in the formation of dioxin and furan (PCDD/F). Copper and iron chloride play a leading role in this process; they serve as source for chlorine. Particularly the Cu^{2+} ions can catalyze the formation of C-Cl bindings and the oxidation of carbon [1].

Technical Combustion Properties

The technical combustion properties of biofuels described below are determining the possibilities and boundaries for thermochemical conversion or they play an important role in this process. Apart from the calorific value, the moisture and ash content as well as the ash-softening behavior of the fuels are here presented and discussed.

Calorific Value

Definition. For the calorific value (heating value) a differentiation between the gross calorific value and the net calorific value is made. Both definitions are given and the differences are discussed.

Definition of net calorific value. The net calorific value (q_{net}) is the specific heat released during complete

oxidation of a fuel without regarding the latent heat by condensation of any water vapor in the flue gas (EN 14918 [10]). It is defined as absolute value of the specific heat (enthalpy) of combustion, in joules, for unit mass of the biofuel burned in oxygen at constant pressure or at constant volume under such conditions that all the water of the reaction products remains as water vapor (hypothetically at a pressure of 0.1 MPa). If the latent heat of the water vapor would be recovered the released heat would be slightly higher. Therefore the net calorific value was formerly been named as "lower calorific value."

Definition of gross calorific value. Opposite to the net calorific value the gross calorific value (q_{gr}) is the specific heat released at complete oxidation of a fuel when the latent heat by condensation of any water vapor in the flue gas is regarded and utilized. In order to do this the flue gas has to be cooled to condense the water vapor. According to the method for determination (EN 14918 [10]) the reference temperature is here set to 25°C. Compared to the net calorific value the heat yield is higher. Therefore, the gross calorific value was formerly named as "higher calorific value."

Difference between gross and net calorific value. The water vapor which is formed during the thermochemical reaction and which is the main reason for the two different definitions of the calorific value is either produced in the chemical reaction of the fuel-bound hydrogen or from the free water in the solid biofuel. For each percentage point of hydrogen content in the dry matter, a latent heat of 218.3 J (related to 1 g of fuel) can be calculated (at 25°C flue gas temperature). For the free and bound water in the biomass, the specific latent heat yield per percentage point of moisture content is 24.43 J, related to 1 g fuel mass.

With these specific values, the deviation between gross and net calorific value can be calculated. The terms can therefore not be used alternatively. For the calculation of the chemically bound fuel energy in a given fuel mass, the net calorific value represents the commonly used parameter. This is because in a heating plant the latent heat via flue gas condensation can only be used if the heat use system is designed for low temperature levels. Furthermore, the combustion unit itself and the chimney system must be able to manage the produced condensates without damage (e.g., condensing boilers). These circumstances are however rarely given. The common use of the net calorific value is therefore a technical convention, which regards the currently given practice of solid fuel conversion systems. This agreement however leads to the paradox, that conversion plants, where the respective technical infrastructure for flue gas condensation and low temperature heat use is given, can thus achieve efficiencies of more than 100% [33]. If the fuel input would be calculated by using then gross calorific value the efficiency would always be below 100%.

The gross calorific value (q_{gr}) of biomass fuels is usually about 6% (bark), 7% (wood), or 7.5% (herbaceous fuels) higher than the net calorific value (q_{net}) (Table 6). This, however, only applies to absolutely dry biomass fuels. For wet fuels this relative difference between the two parameters increases, because the possible heat yield through re-condensation of the produced water vapor is respectively higher (Fig. 8).

Determination. The determination of the gross calorific value – from which afterwards the net calorific value is calculated – is done by the calorimetric method according to EN/TS 14918 [10]. It consists of two separate tests: (1) the combustion of the calibration substance (benzoic acid) and (2) the combustion of the fuel sample itself. For both combustion tests, the same conditions have to be guaranteed.

The determination of the gross calorific value is done by performing a combustion reaction (in pure oxygen under high pressure) after which the combustion products are in defined conditions. This happens in a so-called calorimetric bomb enclosed by a water

Solid Biofuels, Fuels and Their Characteristics. Figure 8 Difference between gross and net calorific value at variable fuel moisture contents

jacket at temperatures of about 25°C (bomb calorimeter). In the water jacket the temperature change can be determined. It represents the released heat during the performed combustion.

After having determined the gross calorific value, the net calorific value is calculated. This is done by reducing the energy content according to the above given correction factors for each percentage point of hydrogen content. In addition, for moisture content a correction is needed by using the above given correction factors. Both corrections account for the heat by condensation usually not recovered (see above). Therefore, an analysis of the hydrogen and the moisture content of the test sample are always needed for the determination of calorific value. Furthermore, the content of oxygen, sulfur, and nitrogen in the fuel is required.

Calorific value of *dry fuels*. For solid biofuels the net calorific value (q_{net}) of the absolutely dry matter is between 16.5 and 19 MJ/kg (Table 6). In practice the rule of thumb applies, it say that about 2.5 kg of air-dried wood represents about 1 l of heating oil (≈10 kWh or ≈36 MJ). For coniferous wood approximately 2% higher net calorific value is observed compared to wood from broad leaf trees [31]. This increase is due to the higher lignin content. For bark from coniferous, another 2% increase is given due to the content of extractives (e.g., resin, oils, and fats). Both component groups are characterized by a relatively high partial calorific value (27.0 and 35.9 MJ/kg), compared to cellulose (about 17.3 MJ/kg) or hemicellulose (about ca. 16.2 MJ/kg) [42].

Wood fuels show a mean increase of net calorific value of about 9% compared to herbaceous fuels. It varies between 16.5 and 17.5 MJ/kg (Fig. 7). Marked differences between grain straw and grain kernels are not given, this also applies to the different grass species. Oil containing fuels (e.g., rapeseed kernels, rapeseed press cake) have a higher calorific value, depending on the individual oil content. This is due to the high calorific value of the oil, which is around 36 MJ/kg (see Table 6).

The calorific value of dry biomass fuels is mainly depending on the content of oxidizable elements (primarily carbon and hydrogen). Additional heat is also released by the oxidation of several main nutrient elements such as sulfur and nitrogen. Due to the usually low contents of these elements, the calorific value of solid biofuels is not influenced significantly. The oxygen content, however, reduces the calorific value because the oxidizable components of oxygen-containing compounds are already available at a higher oxidation state and thus any further oxidation can only provide limited heat yields.

Because of the above interrelation, the net calorific value can be estimated from the knowledge of the elemental composition. This is frequently done by using Eq. 1 (approximation according to BOIE [44]). For biomass, this equation was found best fitting in empirical studies [31]. The net calorific value of dry biomass fuels ($q_{net,\,d}$) in MJ/kg is thus calculated from the element content of carbon (C), hydrogen (H), and the main nutrients sulfur (S) and nitrogen (N). Additionally, the oxygen (O) content in percent of the dry matter is required. When using Eq. 1 a mean error of 4% is given [31]:

$$\left(q_{net,\,d}\right) = 34.8\mathrm{C} + 93.9\mathrm{H} + 10.5\mathrm{S} + 6.3\mathrm{N} - 10.8\mathrm{O} \tag{1}$$

Recently also a new biomass specific estimation for the gross calorific value (dry basis) was derived from 122 data sets [23]. This estimation is given in Eq. 2.

$$\left(q_{gross,\,d}\right) = 1.87\mathrm{C}^2 - 144\mathrm{C} - 2.802\mathrm{H} + 63.8\mathrm{CH} + 129\mathrm{N} + 20.147 \tag{2}$$

$q_{gross,\,d}$ in kJ/kg is given when for carbon (C), hydrogen (H), and nitrogen (N) the values are entered in mass-% from the elementary analyses of the dry biomass fuel.

Impact of moisture content. The highest influence on the net calorific value of a biomass is given by the moisture content. Because moisture content is highly variable, comparisons between fuel types are always made on dry matter basis. Between moisture content and actual calorific value, a linear correlation is given (Fig. 8).

For an estimation of the actual amount of energy, the net calorific value as given at moisture content upon delivery or energetic use is relevant. The respective calculation is done using Eq. 3. $q_{net,\,ar}$ is the net calorific value of the biomass as received (in MJ/kg), M is the given moisture content (in %), $q_{net,\,d}$ is the calorific value of the dry biomass, and the constant

2.443 results from the evaporation heat of water (in MJ/kg), at a temperature of 25°C.

$$q_{\text{net, ar}} = \frac{q_{\text{net, d}}(100 - M) - 2.443M}{100} \quad (3)$$

Impact of ash content. The ash content is an influencing factor, too. This, for example, becomes visible when regarding the reduced net calorific value of sunflower straw and grass cuttings from roadsides compared to wood (Table 6). Figure 9 demonstrates this dependency. The usually limited bandwidth of ash content in the fuels leads to a relatively low impact in calorific value. Only if heavy secondary pollution with minerals occur (e.g., for roadside grass cuttings) this can be different.

Estimating an amount of energy. On the basis of the calorific value and the moisture content of the fuel the amount of energy of a given batch can be calculated. To do this the mass has to be determined. For wood logs, which are mainly traded by the volume (stacked cubic meter) a rough estimation of the mass can be made via conversion into solid cubic meters (massive wood), for example by using the conversion factors given in Table 10. From the solid cubic meters the total wood mass can be calculated, this is done by using mean values for the wood density (Table 11). Because in nature wood is not available at absolutely dry stage the wood densities at given moisture content should be applied. For three different wood types, this conversion is made in Table 4 for several assortments [29].

Solid Biofuels, Fuels and Their Characteristics. Figure 9 Net calorific value as a function of the ash content of wood and herbaceous fuels (related to dry basis) [31]

The conversions for wood logs was performed using uniform factors (1 solid m^3 = 0.65 stacked m^3 wood logs or 1 solid m^3 = 2.43 m^3 wood chips).

The estimation of an amount of energy of a given batch is finally calculated from the determined (or estimated) mass (Table 4), multiplied by the net calorific value of a respective biomass type at the given moisture content (Eq. 3). In Table 5 some planning figures are given for typical biomass fuels and assortments. In order to convert from mega-joule (MJ) into kilowatt hours (kWh) a division by 3.6 is made. One liter of heating oil equivalent (light heating oil) is calculated by dividing the energy content given in kWh by 10 (10 kWh ≈ 1 l heating oil).

The increase of the available fuel energy by drying is usually overestimated. It is fact that the reduction of moisture content leads to a linear increase of the net calorific value (Fig. 8). However, this parameter is related to the fuel mass with water. Thus the drying also reduces the total fuel mass of a given batch. Therefore, the energy increase by drying is not proportional to the increasing net calorific value (as received).

Figure 10 shows the actual impact of drying on the fuel energy of a given cubic meter of stacked or poured bulk material. For example, the drying of spruce wood logs (1 m^3) from 50% to 15% moisture content leads to an fuel energy increase of 135 kWh, this is equivalent to 13% (see variant B in Fig. 10, left figure). For wood chips, e.g., 1 m^3 spruce wood chips, the energy content of freshly harvested material at 50% moisture content increases by 85 kWh if the fuel is dried down to 15% moisture content (i.e., 13% increase, see variant B in Fig. 10, right figure). If, however, air-dried material is assessed the shrinkage has mostly already happened. Then the valuation of the fuel energy in a given cubic meter of stacked or bulk fuel follows variant A in Fig. 10.

Consequently, the drying of biomass fuels can only lead to significant energy increases if the starting point of drying is at high moisture content. At lower moisture content, the drying mainly improves fuel quality and minimizes fuel losses by biological processes during storage. However, drying is often also a requirement to achieve higher combustion temperatures, which can lead to improved burnout (mainly for residential furnaces). For some thermochemical processes drying is even essential (e.g., log wood stoves or updraft gasification).

Solid Biofuels, Fuels and Their Characteristics. Table 4 Mass of various volume assortments and wood types as a function of moisture content. Solid: solid cubic meter; log: wood logs 33 cm stacked; chips: wood chips; sm^3: solid cubic meter

Moisture content in %	Beech			Spruce			Pine		
	solid 1 m^3	log 1 sm^3	chips 1 m^3	solid 1 m^3	log 1 sm^3	chips 1 m^3	solid 1 m^3	log 1 sm^3	chips 1 m^3
	Mass per unit[a] in kg								
0	680	422	280	430	277	177	490	316	202

30	798	495	328	541	349	223	615	397	253
40	930	578	383	631	407	260	718	463	295
50	1,117	694	459	758	489	312	861	556	354

[a]Regarding the fact that wood looses volume while drying; the dry matter densities used here (at 0% moisture) are representing the particle density of dried wood according to Table 11. The respective wood density (incl. moisture) was corrected by the maximum shrinkage (beech 17.9%, spruce 11.9%, pine 12.1%). Between the dry matter density and the density at fiber saturation point (moisture content of 25%, 25% and 21% for beech, spruce, and pine, respectively, see [41]) a linear volume change is assumed

Volatile Matter

All products released from the dry organic substance during pyrolytic decomposition under defined heating conditions are volatile matter. Depending on the fuel type, this fraction is variable. Thus, it is a useful parameter to characterize the fuel's ability to disintegrate into combustible gaseous compounds under heat impact.

The volatile matter content is not an absolute figure. It was defined through convention. It is determined under standardized conditions following EN 15148 [16]. A test portion is heated without contact to ambient air at 900°C ± 10°C for 7 min. The percentage of volatile matter is calculated from the loss in mass of the test portion after deducting the loss in mass due to moisture. In order to achieve a reproducible measurement, the end temperature and the total time of the test have to be monitored carefully. Furthermore, the access to air is to be prevented in order to avoid oxidation.

The volatile matter content allows conclusions on the flame length during combustion or on the gas build-up in gasification. It is thus a relevant characteristic for furnace construction. For example, it can be necessary to increase the amount of secondary air flow if the fuel has high volatile matter content. Also, the combustion space in the furnace has to be larger for high volatile matter contents in order to ensure a sufficiently high residence time of the larger gas volume released.

For lignocellulose fuels, the volatile matter content in the total dry mass is between 74% and 83%. The upper end of this bandwidth is marked by wood fuels (around 82% volatile matter) while for grain straw and grassland cuttings lower values of 74% and 76% are reported (Table 6). In coal the volatile matter is significantly lower. For hard coal a range of 6–45% and for lignite values between 45% and 63% are reported.

Moisture Content

The moisture content is the share of water which can be removed from the fuel under defined conditions. It is usually related to the total mass including water. Sometimes it is also related to the dry matter (e.g., in Germany it is then denominated as "wood moisture" instead of "moisture content"; this term is common in forestry and wood processing industry). However, for energy purposes the moisture content (based on the total mass) is internationally more commonly used [9].

Solid Biofuels, Fuels and Their Characteristics. Table 5 Planning figures for the evaluation of the energy content in a given fuel batch (for wood logs and wood chips the volume change which happens below 25% moisture content was considered) (*OE* oil equivalent, based on light heating oil)

Fuel	Unit	Moisture content *M* in %	Mass (at *M*) in kg	Net calorific value (at *M*) in MJ/kg	Fuel value		
					in MJ	in kWh	in l OE
Wood logs, stacked							
Beech 33 cm, dry	1 sm^3	15	445	15.3	6,797	1,888	189
Beech 33 cm, skin-dry	1 sm^3	30	495	12.1	6,018	1,672	167

Herbaceous (e.g., straw)	1 t	15	1,000	14.3	14,254	3,959	396

It is determined by placing a sample in a drying cabinet at 105°C until constant mass (i.e., drying until no further mass differences can be recorded). This procedure follows the European Standard EN 14774-1 [22].

Natural untreated biomass fuels can also contain some small amount of highly volatile extractives with high-energy content (section "Molecular Composition"). These substances can become volatile during the moisture content determination in a drying cabinet. They are mostly α-pinenes. However, the difference in the measured moisture content is usually below 1%. Only for oil containing materials (e.g., rapeseed press cake) slightly higher deviations are observed when drying is performed at 80°C instead of the usual 105°C [52]. For vast majority of solid biomass fuels the possible error by accepting any volatilization of non-water substances can be neglected in the assessment of a given fuel (e.g., for the determination of the calorific value).

Higher measuring errors are however possible if – as it is realized in practice – rapid methods are applied for moisture content determination. This applies particularly to measuring devices operating according to the electrical conductivity principle as used for wood logs. They usually underestimate the actual moisture content [51]. Rapid test methods for wood chips using capacitance or infrared-reflection methods (NIR) are significantly more accurate. Their measuring inaccuracy is around 3–10% and it remains constant over a large range of moisture contents up to 50% [2, 62].

Solid Biofuels, Fuels and Their Characteristics. Figure 10
Energy content in a stacked cubic meter of wood logs (*left figure*) or in a cubic meter of wood chips (*right figure*) as a function of fuel moisture content. Variant A and B: with and without regarding volume changes by swelling and shrinkage (i.e., for variant A the shrinkage volume is replaced while for variant B the dry matter content remains the same) (*OE* oil equivalent, for light heating oil)

Any false estimation of the moisture content affects the valuation of the fuel energy; this is because the moisture content is the major determinant for the net calorific value at the given drying stage. In nature, totally dry biomass material is not available. Thus the remaining moisture content has to be evaporated during thermochemical conversion. The required energy for this process is obtained from the released process heat and thus it reduces the net energy yield if – as it is common – no condensation of the water vapor in the flue gas is performed.

This impact of moisture content on the net calorific value of the biomass (as received) is shown in Eq. 3. Figure 8 illustrates the described function (section "Calorific Value"). It shows that the net calorific value of wood (here: 18.5 MJ/kg) deceases linearly with rising moisture content. At around 88% moisture content the net calorific value is zero.

In the lower moisture range, an effect on volume of wood is given (section "Physical-Mechanical Properties"). Nevertheless, moisture mainly affects the fuel mass and the combustion temperatures to be achieved under adiabatic conditions. Furthermore, the storability of the fuel is influenced. Moisture content above 16% usually speeds up biological degradation and conversion processes associated with energy losses. Additionally there is an increasing risk of fire due to self-heating and possible self-ignition.

Moisture content of biomass fuels is highly variable, depending on the biomass type, the season and the time between provision and energetic use. The usual bandwidth is between 8% and 65%. Fresh from the forest the moisture content of wood is between 45% and 60%. Hard wood has lower moisture content than soft wood. For coniferous wood, the moisture content is higher in winter when assimilation is low compared to summer [4]. This is not true for broad leaf trees. In short rotation forestry (e.g., poplar, willow) there is an increase of moisture content at the beginning of the vegetation period of 5%-points [31]; this results in higher moisture contents if harvesting is delayed to spring.

Equilibrium moisture content of air-dried wood in Central Europe is given between 10% and 20%, depending on the season. This results in a net calorific value between 14.5 and 16.5 MJ/kg. Herbaceous fuels which are died-off or have been field dried and grain kernels can usually be stored at 15% moisture content. Pellets which follow the European pellet standard EN 14961–2 shall have a maximum moisture content of 10% [18].

Solid Biofuels, Fuels and Their Characteristics. Table 6 Technical combustion properties of untreated natural biomass fuels compared to hard and brown coal (mean values according to [31], for coal: [56])

Biomass fuel	Net calorific value in MJ/kg	Gross calorific value in MJ/kg	Ash content in %	Volatile matter content in %	Ash melting properties		
					DT[a] in °C	HT[a] in °C	FT[b] in °C
Hard coal	29.7[c]		8.3	34.7	1,250		
Brown coal	20.6[c]		5.1	52.1	1,050

Ash Content

The inorganic residue after combustion of a solid biofuels is the ash. It can originate directly from the (unpolluted) fuel or it can be caused by mineral pollutants which have been entrained during the supply chain (e.g., during harvesting, comminution, transport, storage).

The ash content is calculated by the mass of the residue remaining when a sample is heated under defined conditions EN 14775 [20]. This is done by rising the oven temperature over 30–50 min to 250°C and then keeping the temperature constant over 60 min to allow any volatiles to leave the sample before combustion. Then the oven temperature rises at a constant increase of 10 K/min to 550°C, where it remains constant over minimum of 120 min.

In previous test methods (e.g., ISO 1171) the ash determination was performed at a much higher temperature of 815°C, which is still common for coal fuels. The results between the two methods can deviate because at high temperatures inorganic matter can partly become volatile by further oxidation or a release of CO_2 from the disintegration of carbonates can lead to material losses. This systematic deviation can be between zero and several percentage points, depending on the fuel type and ash content level [31].

Of all biomass fuels wood has the lowest ash content in the dry matter (about 0.5%). Higher values are thus usually due to secondary pollution (e.g., by adhering soil). This can be read from the frequency distribution curve for the ash content following a pattern with a peak on the left side (Fig. 7). Accordingly, ash content above 1% is rare for wood alone (without needles or leaves). Only wood from short rotation forestry (e.g., poplar, willow) contains usually higher amounts of ash (about 2%). This is due to the higher bark content of young wood and because bark contains more ash than the heartwood. Bark from spruce, for example, has ash content between 2.5% and 5% (Table 6). The ash content is even higher for most herbaceous fuels.

The ash content of a fuel has an environmental impact and it influences the technical design of a furnace. Higher ash content in the fuel can lead to increased particle emissions or to further requirements for particle separation. Additionally, special technical solutions may be required for the deashing and cleaning of heat exchanger surfaces. Furthermore, the higher efforts for ash handling and disposal are increasing the process costs.

In the ash, several elements described in section "Elemental Composition" are accumulated. These elements are mainly calcium (Ca), magnesium (Mg), potassium (K), phosphorous (P), and sodium (Na). The mean composition of coarse ash from combustion of wood is about 42% CaO, about 6% K_2O, about 6% MgO, about 3% P_2O_5, and about 1% Na_2O. Additionally there is a minor content of iron (Fe) and manganese (Mn). Ashes from straw fuels also have higher shares of K_2O and P_2O_5.

Ash Melting Properties

Due to the induced processes during thermochemical conversion, the physical properties of the ash are modified. Depending on the temperature level, phenomenon like sinterification or even a complete meltdown of ash particles can occur in the fire bed. This can be associated with severe technical disadvantages in the conversion plant and it has to be considered for the design of the combustion process.

The ash melting behavior is depending on the ash constituents and it is thus directly correlated with the fuel composition. Therefore, the ash melting behavior is listed among the fuel-specific properties. As measuring parameters, four characteristic temperatures are used. At these temperatures certain observations concerning ash modifications are made. They are the Shrinkage Starting Temperature (SST), the Deformation Temperature (DT), the Hemisphere Temperature (HT), and the Flow Temperature (FT).

Their determination is done following CEN/TS 15370–1 [15]. A fuel sample is first incinerated according to the principles for the ash content determination (i.e., at 550°C [20]), then the ash is milled and mixed with an additive (water, dextrin, or ethanol) before it is pressed to a sharp edged cylindrical sample piece of 3–5 mm height and the same diameter. The produced test piece is then heated in a defined temperature rise while the observed changes are recorded via a digital camera. The temperatures at which the sample piece is noticeably changing by softening and deformation describe the ash melting behavior. They are defined as follows:

- *Shrinkage starting temperature, SST.* At this temperature the shrinking of the test piece occurs. This temperature is defined as when the area of the test piece falls below 95% of the test piece area at 550°C (Fig. 11). Shrinking may be due to liberation of carbon dioxide, volatile alkali compounds, or sintering. The shrinkage is not always easily detectable but it provides additional information on the

Solid Biofuels, Fuels and Their Characteristics. Figure 11
Characteristic phases during the melting process of a cylindrical ash sample piece according to the standard test method [15] (Original sample = form and size at 550°C; *H* height of sample piece, r_2 radius of hemisphere)

fuel ash behavior. Currently few data are available for shrinkage; Table 6 is therefore incomplete concerning this new parameter.

- *Deformation temperature, DT.* At this temperature the first signs of rounding of the edges due to melting of the test piece occur (Fig. 11).
- *Hemisphere temperature, HT.* It is the temperature at which the test piece forms approximately a hemisphere; this is given when the height becomes equal to half the base diameter (Fig. 11).
- *Flow temperature, FT.* At the flow temperature the ash is spread out over the supporting tile in a layer; the height of this layer is half of the height of the test piece at the hemisphere temperature (Fig. 11).

For fuels with a low ash melting point a high risk of slag deposition and adhesion in the conversion plant is given (e.g., in the combustion chamber, at the grate, on heat exchanger surfaces). Such coatings can lead to blockages, breakdowns, and to an inhibited combustion air supply. They also promote high temperature corrosion. By complex technical attachments, such as water-cooled grates or furnace beds, moving elements in the fire bed, flue gas recirculation, slag breaking elements, fuel turbulence, or fuel additives, the problems can be avoided.

Because wood and bark show high deformation temperatures of about 1,300°C to more than 1,400°C they are usually uncritical in most energetic processes (Table 6). For herbaceous fuels, however, the deformation temperature is almost consistently below 1,200°C. Thus, the described disadvantages bear a technical risk for combustion. For grain straw, for example, a mean deformation temperature of 900–950°C is observed (Fig. 7). However, most critical are grain kernels, where even the flow temperature is usually below 900°C (Table 6).

Similar to the calorific value, the ash deformation temperature is depending on the content of relevant elements. In this context, calcium has a positive impact because it raises the critical temperatures. For potassium, the opposite effect is observed. From these correlations it can be concluded that the ash melting behavior can be improved by mixing the fuel with calcium-containing additives (lime) or by using additives which capture alkaline compounds (e.g., kaolin) [57]. On the other side, the depletion of critical elements from the fuel is a different path for improvements. Therefore the leaching of potassium by precipitation during field-drying or the ripening phase of the crop (e.g., for straw or hay) can have a positive effect under practical conditions. Thus, the ash deformation temperature can be raised in a magnitude of 100–150°C [31].

Physical-Mechanical Properties

Physical-mechanical fuel parameters mainly describe those properties determined during the harvesting and upgrading process. They comprise characteristics such as the surface properties, geometry, size and size distribution, fine matter content, flowing and bridging properties, resistance to abrasion, bulk, and particle density. As for the parameters described in section "Technical Combustion Properties," international standards for their determination are also available for most parameters described here.

In opposite to the fuel composition parameters (section "Fuel Composition"), the technical and physical-mechanical characteristics are largely interacting among each other. The moisture content is also playing a major role in this context of interactions (Fig. 12) and it influences the physical mechanical properties. These parameters are presented and discussed in below.

Shape and Dimensions

Solid biofuels can be characterized by their shape, which is described by length, height, and width, or by the volume and the geometrical form (i.e., geometric solid).

For hand charged furnaces, specific requirements concerning the maximum fuel expansion are usually given for each furnace type. Firewood can, for example, have a maximum end-user size of 1 m (for meter-wood boilers). But mostly such wood logs are cut one, two, or three times to pieces of 50, 33, or 25 cm in length, depending on the depth of the combustion chamber. Log lengths of 33 cm are here clearly predominant.

For briquettes, produced by mechanical compaction of biomass, variable sizes and shapes are available on the market today. A differentiation between pellets and briquettes is here mainly made by the diameter. From a diameter above 25 mm they are briquettes, below this diameter they are pellets [17].

For pellets European standard size classes are defined:

- Class D06: diameter $\leq$ 6 mm $\pm$ 1.0 mm und length (L) 3.15 $\leq$ L $\leq$ 40 mm

Solid Biofuels, Fuels and Their Characteristics. Figure 12 Interactions between physical-mechanical and technical combustion properties of solid biomass fuels [28]

- Class D08: diameter $\leq$ 8 mm $\pm$ 1.0 mm und length (L) 3.15 $\leq$ L $\leq$ 40 mm
- Class D10: diameter $\leq$ 10 mm $\pm$ 1.0 mm und length (L) 3.15 $\leq$ L $\leq$ 40 mm
- Class D12: diameter $\leq$ 12 mm $\pm$ 1.0 mm und length (L) 3.15 $\leq$ L $\leq$ 40 mm
- Class D25: diameter $\leq$ 25 mm $\pm$ 1.0 mm und length (L) 10 $\leq$ L $\leq$ 50 mm

In addition, herbaceous fuels can be compressed to either round or square bales of variable dimensions (Table 7). Recently also pellets und briquettes are produced. Loose unchopped material is not directly applied as a fuel, but the comminution to chopped material (pieces of 2–40 mm length) can lead to similar mechanization benefits as for wood chips.

Size Classes and Fine Matter

The flow and transport properties of pourable materials are also described by the particle size distribution and the share of fine materials (e.g., by abrasion of pellets). To describe the physical properties of a given wood chip batch, for example, the determination of a mean particle diameter or the mean length alone is not sufficient. Rather the information about the share of certain size classes is needed for proper description. Therefore, a classification using several size classes is useful. Such a system is described in Table 8.

The particle size distribution is relevant for several technical reasons. A larger impact of an unsuitable size distribution is given for mechanical systems in silo emptying, conveying, or charging systems of thermochemical conversion plants. Too long particles can, for

Solid Biofuels, Fuels and Their Characteristics. Table 7 Geometry and dimensions of various compressed herbaceous fuels

Fuel form	Geometry	Dimension in cm
Small square bales	Cuboid	40 × 50 × 50–120
Round bales	Cylindrical	Ø 80–200 × 120–170
Big square bales	Cuboid	80–130 × 80–130 × 120–250
Highly compressed fuels: pellets briquettes	Cylindrical, cuboid, etc.	Ø 0.3–2 × variable length variable forms

Solid Biofuels, Fuels and Their Characteristics. Table 8 Requirements for size classes of wood chips according to the European wood chip standard EN 14961-4 [19]

Size class	Minimum 75 wt% in main fraction, mm[a]	Fines fraction, wt % (<3.15 mm)	Coarse fraction, (wt%), max. length of particle (mm), max. cross-sectional area (cm^2)
P16A	$3.15 \leq P \leq 16$ mm	≤12%	≤ 3% > 16 mm, and all < 31.5 mm The cross-sectional area of the oversized particles <1 cm^2
P16B	$3.15 \leq P \leq 16$ mm	≤12%	≤ 3% > 45 mm and all <120 mm The cross-sectional area of the oversized particles <1 cm^2
P31.5	$8 \leq P \leq 31.5$ mm	≤8%	≤ 6% > 45 mm, and all <120 mm The cross-sectional area of the oversized particles <2 cm^2
P45A	$8 \leq P \leq 45$ mm	≤8%	≤ 6% > 63 mm and maximum 3.5% > 100 mm, all <120 mm The cross sectional area of the oversized particles <5 cm^2

[a]The numerical values (P-class) for dimension refer to the particle sizes (at least 75 wt%) passing through the mentioned round hole sieve size

example, lead to blockages and damages of the conveyor and they can lower the material throughput. In addition, the flowability and the resistance to air flow during ventilation or drying are affected. Furthermore, the tendency to form a bridge during transhipment (e.g., at the bottom of a silo) is determined by an unsuitable size distribution. Finally, also the possibility for fine material to disintegrate from the bulk (e.g., during transportation) and thus to increase non-uniformity within the fuel bulk is facilitated by an unfavorable size distribution.

The determination of particle size distribution is performed by sieving. This is done using a set of horizontally shaking sieves placed above each other. The particles of a sample are then passed through the screen set starting with the largest hole apertures. Then they are separated according to their size in the respective screen, which is finally weighed. The share of mass in each fraction, assuming that particle density of smaller and larger particles is consistent, then determines the size distribution. For the determination of a particle size distribution according to the European wood chip standard a set of screens with round holes was selected (hole diameters of 3.15, 8, 16, 31.5, 45, and 63 mm). Additionally it can be useful to add a 1 mm (mesh wire sieve) [21].

During sieving the particles are rather separated by their width than by their length. Therefore, a considerable amount of particles which are significantly longer than the screen hole aperture width are found in one of the following size class. The median value of a size distribution determined by horizontal screening is therefore mostly only half of the value to be found if the median value was determined from the distribution of the actual lengths (maximum particle expansion) [34]. In particular, higher shares of overlong particles are always determined when the particles largely differ from an ideal sphere shape. This is, for example, the case when the sample is a hog fuel type produced by using blunt tools rather than sharp cutting knifes as applied in wood chip production [34]. Hog fuel usually has a largely higher length-diameter ratio.

Consequently, the classification during sieving is mainly done by sorting according to the maximum particle diameter. However, for the assessment of mechanical fuel properties the results from a size distribution determination by length (i.e., largest expansion) would be the more relevant parameter. This approach would also be more decisive for the mechanical properties of the fuel. But at sufficient accuracy such a measurement can only be performed using continuous image analysis [34]. However, this method is still not widely available. Therefore, the results from a particle size distribution analysis by screening according to EN 15149–1 [21] shall not be interpreted as absolute figures.

During the particle size analysis, the amount of fine material is also determined. It is characterized as the fraction of particles falling through screen hole apertures of about 3.15 or 1.0 mm diameter (internationally

inconsistent). The share of fines is often regarded as an independent fuel parameter. This particle fraction is particularly relevant for wood pellets, because dry wood dust can lead to drastic dust formation during pneumatic conveying. It can also increase the risk of explosion by deflagration.

Flowing and Bridging Properties

The fuel extraction from silos and day storages can be inhibited by technical problems created by unfavorable flow properties. The formation of hollow spaces (bridges or arches) or shafts in a silo is possible (Fig. 13). The latter is associated with a core flow of the material instead of the desired mass flow. Both phenomenons finally lead to the problem that the fuel will sooner or later not any more fall downward to the conveyors or the flow becomes unsteady. Frequently there is also an alternating build-up and breakdown of bridges or shafts. Furthermore, the volume of the container is incompletely used and the retention time of the fuel compartments is inhomogeneous. This means that the fuel remains much longer in the dead layers of a shaft silo and this can lead to severe quality losses. The described phenomenons can also be the reason for fuel segregation by particle size, density, and form; a high quality variation is then a consequence.

Solid Biofuels, Fuels and Their Characteristics. Figure 13 Phenomenons of unfavorable flowability of fuels [55]

The problems created by unsuitable flow properties are increasing with the moisture content, the filling depth, and the share of overlong and branched particles while uniform particle sizes and smooth surfaces (e.g., pellets, wood chips without bark) are beneficial [36, 43]. A supplementary sorting to achieve uniform material conditions can thus lead to considerable improvements of the flow properties.

Usual shear cells are not suitable for the determination of flow properties due to the sometimes large particle sizes. Therefore a method for a direct determination of the bridging properties was developed. It uses a special apparatus where a fuel sample of 1.65 m^3 is forced to form a bridge over an opening slot under controlled conditions. The opening width of the slot at the moment when the fuel bridge collapses is taken as a measure for the bridge building properties of the sample. This requires a frictionless opening of the bottom slot. It is achieved by the fact that a flat steel bottom is sliding away underneath a PVC mat on which the fuel sample is resting [36].

Bulk Density

The required storage and transport volume is determined by the bulk density of a pourable fuel or by the stacked density of logs and briquettes. The respective definitions and conversion factors are described below.

Definition. The bulk density is defined as the quotient of the mass of a material filled into a container and the filling volume of the container. The hollow space between the fuel particles is thus not reducing the volume; this also applies to the staked density of wood logs. Typical density values are given in Table 9.

Determination. For determination of the bulk density a sample is being filled in a defined mode into a cylindrical container of 50 l volume (EN 15103 [11]). The container is filled over the edge and is then exposed to controlled shock by dropping it three times from 150 mm height onto a wooden floor. Then the filling volume created by the shock operation is refilled and leveled to the rim of the container. Then the net weight is determined and related to the container volume.

Settling factor. The defined shock exposure operation leads to a certain volume reduction due to compaction effects occurring during the supply chain. These

Solid Biofuels, Fuels and Their Characteristics. Table 9 Typical bulk and staked densities of biomass fuels at a moisture content of 15%

Wood fuels		Density in kg/m^3	Herbaceous fuels		Density in kg/m^3
Wood logs (stacked)	Beech	445	Round bale	Straw	85
	Spruce	305		Hay	100
Wood chips	Soft wood	200	Square bale	Straw, miscanthus	140
				Hay	160
	Hard wood	280		Whole grain crop	190
Wood bark	(coniferous)	175	Chopped	Miscanthus	110
Saw dust		160		Whole grain crop	150
Shavings		90	Grain kernels		750
Wood pellets		650	Pellets		550

compaction effects are mainly due the fact that the fuel is usually transported and/or stored in containers or silos much larger than the measuring container chosen for the method described here. Thus in practice the higher mass load in a storage leads to an increased load pressure and to fuel settling, which can additionally be enhanced by the vibrations during transportation. Furthermore, filling or unloading operations in practice usually apply a higher falling depth than the one chosen for the here performed test. This will also result in a respectively higher compaction due to the increased kinetic energy of the particles falling. The procedure with applying a controlled shock to the sample is thus believed to reflect the practically prevailing bulk density in a better way than a method without shock. This is particularly true when the mass of a delivered fuel has to be estimated from the volume load of a transporting vehicle, which is a common procedure in many countries.

The difference between a measurement with and without shock can be interpreted as the settling factor. The measured results for this factor are given in Fig. 14 for several biomass fuels. It shows that the compaction effect during handling and transhipment is low for wood pellets or grain kernels (only 6–7% settling). However, this effect is largely higher when chopped herbaceous fuel such as Miscanthus is regarded (max. 18% settling). For wood chips the bulk density increase due to controlled shock is around 11%; differences between high or low density wood chips are negligible here (fuels above 180 kg dry matter per m^3 were in Fig. 14 defined as high density fuels).

Transformation to other moisture content bases. For comparability the determined densities should be converted to uniform moisture content or to dry basis. If for practical reasons the swelling and shrinkage is here disregarded, the dry matter based bulk density (D_d) is calculated from the actual bulk density as received (D_{ar}) by regarding the given moisture content (M) according to Eq. 4.

$$D_d = D_{ar} \times \frac{100 - M_{ar}}{100} \tag{4}$$

Equation 4 disregards shrinkage or expansion, which usually cause significant deviations when the sample is measured at different drying stages. For uncompressed wood fuels, these volume changes usually occur at moisture contents below the fiber saturation point, which is at around 25%, depending on the wood species. A true comparison between fuel samples would therefore require a determination at similar moisture contents. Alternatively, a correction factor can be used if sample materials of different moisture content shall be compared and at least one sample is below the fiber saturation point. Here the usual effect of swelling or shrinkage is in the order of around 0.7% volume change per percentage point of moisture difference [32].

Conversion of volumes. In practice, a fuel volume often needs to be converted to another volume basis.

Solid Biofuels, Fuels and Their Characteristics. Table 10 Conversion factors between different wood log assortments (with bark) [37] (sm^3: stacked cubic meter)

Wood type	Solid wood volume in solid m^3	Round wood, stacked in sm^3	1-m logs, split, stacked in sm^3	33-cm logs, split stacked in sm^3	33-cm logs, loose in m^3
For 1 solid cubic meter (with bark)					
Beech	1.00	1.70	1.98	1.61	2.38
Spruce	1.00	1.55	1.80	1.55	2.52
For 1 cubic meter of round wood					
Beech	0.59	1.00	1.17	0.95	1.40
Spruce	0.65	1.00	1.16	1.00	1.63
For 1 cubic meter of 1-m logs (split)					
Beech	0.50	0.86	1.00	0.81	1.20
Spruce	0.56	0.86	1.00	0.86	1.40
For 1 cubic meter of 33-cm logs (split)					
Beech	0.62	1.05	1.23	1.00	1.48
Spruce	0.64	1.00	1.16	1.00	1.62
For 1 cubic meter of 33-cm logs (split)					
Beech	0.42	0.71	0.83	0.68	1.00
Spruce	0.40	0.62	0.72	0.62	1.00

In the untreated state wood is often rated by the solid cubic meter (i.e., without regarding any hollow space). However, when supplied to the final customer as wood logs, the fuel is usually rated as staked or bulk cubic meter. For conversion from solid cubic meters (solid m^3) to staked cubic meters (sm^3) a general factor of 1.43 had in the past widely been used (i.e., 1 solid m^3 is 1.43 sm^3). However, a more differentiated calculation is useful, particularly because the general conversion factor of 1.43 is too low even for very densely piled oven-ready and dry wood logs [37]. Table 10 shows that a staked cubic meter of firewood at 33 cm length is in average produced from 0.62 m^3 of solid beech wood or from 0.64 m^3 of spruce wood. For a single cubic meter of stacked 33 cm-logs a volume of 1.23 sm^3 of 1 m-logs is required. Significantly different conversion factors between spruce and beech wood also observed within the loose logwood assortment (Table 10).

In reality, however, the conversion factors can largely differ from the figures given in Table 10, depending on the processing technology and the physical growth shape of the tree. This applies particularly to the conversion factors from solid to any form of stacked cubic meter.

For wood chips, the conversion from massive (solid) cubic meter to the volume of bulk material is usually done using a general factor [5]. It is:

- 1 solid cubic meter (m^3) (massive wood) $\approx$ 2.43 m^3 wood chips
- 1 stacked cubic meter (sm^3) of stacked wood $\approx$ 1.7 m^3 wood chips

Larger deviations from this general factor are also likely. But to date no differentiations between wood species or between the applied comminution technologies can yet be made. The shrinkage by drying or the volume losses by shock or vibration (settling factor) can be estimated using the data given in the previous chapters.

Energy density. When assessing biofuels and their specific storage room demand the term "energy density" is sometimes used. It is defined as the respective

Solid Biofuels, Fuels and Their Characteristics. Figure 14 Relative effect of shock impact compared to a non-shock application in bulk density determination ("settling factor") derived from measurements in a 50-l-container, which is dropped three times before refilling, surface leveling and weighing [32]

Solid Biofuels, Fuels and Their Characteristics. Figure 15 Specific mass and storage room demand of different energy sources (for solid fuels a moisture content of 15% is assumed) [26]

mass or volume needed to provide a given unit of fuel energy at a given moisture content. A comparison of selected fuels regarding their energy density is given in Fig. 15.

Particle Density

The particle density of a fuel describes the actual material density (i.e., without regarding the hollow space between the particles). It influences the bulk or stacked density and some combustion properties (e.g., the specific heat transfer rate): Also, the pneumatic transportability is depending on it. Physically the particle density can only be influenced by compaction to pellets or briquettes.

When determining the particle density of compressed biomass fuels (pellets or briquettes), the volume of a single particle is first determined by measuring its buoyancy in a liquid (water with wetting agent) according to EN 15150 [12]. Then the mass as determined in ambient air is set into relation to this volume.

Table 11 shows the particle densities of various wood species given at an absolutely dry stage. When the moisture content of fiber saturation is given (ca. 19–25%) the volume is higher. The difference is the so-called shrinkage factor. This has a respective effect on the particle density of the wetter fuel. The volume change by shrinkage is 17.9% and 12.2% for beech and oak or 11.9% and 12.1% for spruce and pine [41].

The parameter particle density is sometimes used to characterize the intensity and quality of a compaction process. A high particle density indicates a high hardness and thus only little risk of abrasion or fine material losses. However, a significant correlation between particle density and resistance to abrasion has never been clearly observed [58]. For pellets therefore the direct determination of abrasion using a mechanical test method is today preferred (section "Resistance to Abrasion").

Compared to compressed materials the particle density of grain kernels is usually not lower. For oat kernels (with husk), for example, the density is around 1.0 g/cm^3 while wheat kernels without husks have an average density of 1.35 g/cm^3. The density of a grain

Solid Biofuels, Fuels and Their Characteristics. Table 11 Particle density (including shrinkage) of absolutely dry wood [41, 49]

Soft wood (max. 0.55 g/cm^3)		Hard wood (above 0.55 g/cm^3)	
Spruce	0.43 g/cm^3	Oak	0.67 g/cm^3
Fir	0.41 g/cm^3	Sycamore	0.50 g/cm^3
Pine	0.49 g/cm^3	Ash	0.67 g/cm^3
Douglas fir	0.47 g/cm^3	Beech	0.68 g/cm^3
Larch	0.55 g/cm^3	Birch	0.64 g/cm^3
Alder	0.49 g/cm^3	White beech	0.75 g/cm^3
Lime tree	0.49 g/cm^3	Black pine	0.56 g/cm^3
Aspen	0.45 g/cm^3	Hazelnut	0.56 g/cm^3
Poplar	0.41 g/cm^3	Black locust acacia	0.73 g/cm^3
Willow	0.52 g/cm^3	Elm	0.64 g/cm^3

haulm is however significantly lower, for wheat straw it is in average around 0.20 g/cm^3 (considering only wall material) [30].

Resistance to Abrasion

Resistance to abrasion describes the coherence of fuel particles in a compressed material (pellets or briquettes). This property is mainly important for all processes of loading and transhipment, where the material is exposed to mechanical wear, and where small particles are removed and can thus contribute to the release of fine dust. Such dust is usually formed when a silo or storage is pneumatically filled with pellets, because fine wood dust can easily penetrate through small cracks in silos or rooms. With briquettes, an unsuitable mechanical strength can lead to a breaking of the material during hand charging or transport. Moreover, it leads to dirt accumulation near the furnace (e.g., in the living space). A high dust formation can lead to explosion reactions when either a high heat impact or freely flying sparks are given. This can happen in the storage, the feeding system, or within the furnace itself.

For the determination of resistance to abrasion a standard method is applied (EN 15210–1 [13]). A sieved pellet sample is filled into a dust-tight rotating test box of a rectangular geometry (300 × 300 × 125 mm). In the inside, the box is equipped with a baffle. The sample is then exposed to defined mechanical wear by rotating it in the box over 10 min at a speed of 50 rpm. Then the sample is again screened using the previously applied round hole sieve (3.15 mm hole diameter) and the weight difference to the original sample is determined. For high quality pellets, the pellet mass remaining on the screen after the mechanical treatment should be above 97.5%. Such a durability is then classified by "DU97.5" according to the EN 14961–1 [17]. Further quality steps are, for example, DU96.5 and DU95.0 with less remaining mass fraction after the described mechanical treatment and sieving.

For briquettes the mechanical treatment is similar (EN 15210–2 [14]). Instead of the rectangular tumbling chamber, a lying cylinder is used for rotating the sample (diameter and height both being 598 mm). An inbuilt baffle ensures that the sample is exposed to significant mechanical stress over 5 min of rotation at 21 rpm [14]. The applied sample mass of 2 kg is higher because of the larger briquettes.

The stability of pellets or briquettes during mechanical stress depends on several factors. They are, for example, the form (for briquette), the chosen compaction method, or the use of any binding agents. An unsuitable cooling after compaction reduces the mechanical strength. High air humidity during storage can lead to an increased fuel moisture content which also lowers the mechanical stability [28]. The type of material itself also gives a decisive role, because composition and macromolecular structure can influence the effectiveness of the binding forces. Therefore the stability of straw pellets is usually lower than of wood pellets [58].

Future Directions

In some regions, biomass fuels are already becoming scarce. Countries with high ambitions or obligations concerning their future share of renewable energy or CO_2-reduction goals are therefore increasingly depending on imported biomass. In such a scenario, the energetic density is a decisive criterion. Therefore, pelletization of biomass is an increasingly important technical option to realize long-distant trade relations. International standardization in this field is now providing the necessary directions and enables

the introduction of sound and comprehensive quality assurance systems.

The growing importance of pelletization does not only apply to wood fuels but also to agricultural residues and non-woody energy crops. However, the scope of using herbaceous fuels is today still limited due to their unfavorable properties. The upcoming search for new resources therefore needs to be associated with developing and applying new methods for fuel improvements. This can, for example, be the application of additives or applying other pretreatment measures before pelletizing. Desirable changes in fuel composition can also be achieved by depleting pollutants through active leaching with water or by thermochemical pretreatment measures such as heat application (torrefaction) or the use of steam and pressure (hydrothermal carbonization). In such cases, largely homogenized high-value fuels are produced and not only their chemical composition but also their physical-mechanical properties are thus adapted to new requirements. This development can enable to establish new technical applications for the fuel (e.g., higher rates of co-combustion with fossil coal).

In general, the now introduced European and ISO-standards for biomass are about to boost possibilities for quality increases and they allow the introduction of high grade market fuels which finally can stimulate technologically and environmentally more sophisticated conversion routes. Nevertheless, in view of the increasing depletion of existing potentials – particularly for low value biomass residues and by-products – the future challenge is to select, improve, and process suitable energy crops, and to monitor all quality relevant influences in order to achieve consistently high biomass fuel quality. However, the knowledge base for such comprehensive quality manipulations is still thin and sound, and predictable technical measures are yet few.

Acceleration method Generally speaking, there is no appropriate acceleration method for stack performance degradation as a whole. Therefore, individual factors should be carefully accelerated to know the degradation phenomena. One degradation phenomena should consist of several processes having different activation processes. It is highly required to have an acceleration method which should not create additional sources of different origin and mask the original sources of degradation to be investigated.

Cr poisoning Catastrophic degradation of lanthanum manganite–based cathode due to the chromium–oxygen vapors emitted from Cr_2O_3 oxide scale as a result of reaction with (humidified) air. Cr poisoning for other cathodes such as cobaltite or ferrites are completely different in mechanism. The $SrCrO_4$ formation is a key phenomena causing the lowering in cathode performance.

EVD cells Sealless tubular cells fabricated by the electrochemical vapor deposition (EVD) technique. The durability is excellent, whereas the fabrication

cost is expected to be quite high. This cell can be regarded as the standard cell when the relation among durability, efficiency, and cost is considered.

First-generation cells Cells to be operated in the temperature region of 900–1,000°C. Usually oxide interconnects are used together with electrolyte made of YSZ. Since materials compatibility is severe at higher temperatures, stable lanthanum manganite-base cathode is adopted, whereas nickel anodes are used in a similar manner to other types. Electrolyte-self-support or cathode-support types are adopted.

Metal-support cells Cells are fabricated on metal substrates. Compared with ceramic substrates, adoptable fabrication conditions are limited to prevent metals from being oxidized severely. Instead, metals as a main structural component provide many benefits such as better stability against thermal shocks and milder temperature distribution inside the stacks, etc.

Redox stability When anode-support cells are adopted, the mechanical behavior of anode substrate becomes important. During redox cycles, an anode layer is expanded to destroy the nickel connection or to make cracks on YSZ framework/YSZ electrolyte plate.

Reliability versus cost reduction In many cases, achievement of reliability is in trade-off relation to cost reduction. To overcome this, it is required to make breakthroughs in the fabrication technologies.

Second-generation cells Cells to be operated in the temperature region of around 800°C. Metal interconnects are used together with anode-support cells and sealing materials. The active cathode such as LSCF (lanthanum strontium cobaltite ferrites) is used so that the durability is one of the main issues.

Stress caused by volume changes Mechanical stability is dominated by volume changes in components; these are caused by thermal expansion with temperature, chemical volume change due to the valence change within the same lattice at the constant temperature.

Sulfur poisoning Degradation of nickel-cermet anodes due to the adsorption of sulfur originated from H_2S in fuels. An initial drop in performance after introducing H_2S is maintained without further degradation. After switching back to the normal fuels without sulfur, anode performance is recovered slowly. In cathodes, some degradation is observed due to the contamination as SO_2/SO_3; in such a case, $SrSO_4$ is formed.

Third-generation cells Cells to be operated below 800°C. Instead of oxide ceramics, metal is used to support cells. Fabrication technique is most challenging.

Definition of the Subject

Solid Oxide Fuel Cells (SOFCs) are devices of converting chemical energy (fuels) into electrical energy using an oxide ion conducting materials as electrolyte together with cathode for oxygen incorporation process and anode for oxidation of fuels. For fuel cells to be continuously operated, there arise four flows inside fuel cells: air flow and fuel flow, electrical current, and heat flow. Historically, only a small number of SOFC stack types have been successfully established because it is rather difficult to construct electrochemical cells/stacks with solid materials alone in keeping good electrical contacts among components, good gaseous permeability along the gas channels, or complete gaseous tightness across dense parts such as electrolyte and interconnects [1–3]. This leads to additional requirements concerning the chemical compatibility [4] among the cell components and the mechanical stability [5] of stack as a whole during fabrication and long-term operation including a certain number of thermal cycles. This makes materials selection difficult. Not only the functional properties but also the compatibility with adjacent materials is quite important. Durability and reliability of SOFC stacks are therefore strongly dependent on such materials compatibility [6]. Stress comes from any volume changes in the cell components; for example, thermal expansion mismatch, chemical volume expansion due to changes in valence state [7], volume change on precipitation of products of reactive diffusion or reaction with gaseous impurities, pore formation, etc. These changes may cause the mechanical instability among the stack components and also affecting the functional parts of cells; that is, the electrical path can be damaged or the gaseous permeability through gas channel to and from the electrochemical reaction sites are influenced. When cracks are formed inside

electrolytes or interconnects, fuels and oxidants will meet and burn without generating electricity, causing local heating. The electrochemical performance may also be degraded directly by gaseous impurities attacking the electrochemical reaction sites which are located at the electrode/electrolyte interface region. Changes in microstructure of electrodes also lead to degradation of performance; nickel sintering is a typical example. In these processes, solid-state diffusion makes important contribution [8].

Historically speaking, reliability issues are always associated with an important feature that developments of stack design, fabrication methods, and cell materials are mutually related with each other. Even when the same materials are used in different stack designs, a fabrication method must be different so that materials compatibility appears in different manners. Main issues in the early stage of research and development were interface stability between cathode and electrolyte [9], interconnect chemistry associated with sinterability of lanthanum chromites [10], and chemical volume expansion [7]. Sealless tubular cells fabricated with electrochemical vapor deposition (EVD) [11, 12] were the first ones which have been successfully developed by solving those issues [13, 14]. Durability of the sealless tubular cells was found to be excellent as shown in quite low degradation rates: 0.1%/1,000 h for cell performance and less than 0.1%/1,000 h for system performance at the operation temperature of 1,000°C [10]. Demerits of tubular cells, however, were analyzed as their low-volume power density and high fabrication cost [15]. These sealless tubular cells are recognized as the first-generation cells. After this success, many attempts have been made to overcome those demerits by testing new materials, new cell designs, and new stack designs. The most typical ones can be called as the second-generation cells which are operated around 750–800°C. Here, metal interconnects were adopted instead of oxide interconnect, active cathodes such as lanthanum strontium cobaltites (LSC) or lanthanum strontium cobaltite ferrites (LSCF) [16] were used instead of stable but less active lanthanum strontium manganites (LSM), and an anode-support-type cell design was adopted. As a result, performance of such second-generation cells has been rapidly improved and in many cases has become much better than that of the first generation. On the other hand, durability was not better because metal interconnects and active cathodes were adopted in spite of their low chemical stability [17]. More recently, the third generation based on the metal support cells [18–20] has attracted much attention, because of its expecting low costs and lower operating temperatures. Based on the idea adopted for this generation, nickel can be regarded as a rather expensive material. Instead, cheaper stainless steel should be utilized as a main cell component. This inevitably leads to a requirement that appropriate fabrication methods should be developed so as to fabricate metal-support cells with a reasonable cost. In other words, chemical stability becomes a big issue even in the fabrication processes.

Introduction

The most important features associated with fuel cell technologies are energy conversion efficiency, durability (or life time), and cost. These are common characteristic features among various fuel cells such as phosphoric acid fuel cells (PAFC), molten carbonate fuel cells (MCFC), polymer electrolyte fuel cells (PEFC), and solid oxide fuel cells (SOFC). For comparison among fuel cells, applications in which fuel cells are utilized are important aspects of fuel cells: stationary application in several 100 kW or larger, small stationary applications for residential houses, and automotive or mobile applications.

For the first stationary application, comparison was made in 1980s–mid-1990s among PAFC, MCFC, and SOFC. Efficiency, based on the methane fuel, was regarded as about 40% for PAFC operated at 180°C, 45% for MCFC operated at 650°C and 40% for SOFC operated at 1,000°C when the first attempt by Westinghouse for tubular cells was succeeded [21]. Later, it is clarified that the higher efficiency of MCFC compared with SOFC is due mainly to the operation temperature. Actually, with decreasing operation temperature of SOFCs, the efficiency increases even for SOFCs. The most surprisingly impressive achievement of Westinghouse's SOFCs is their stable performance for a long period of operation time, although their fabrication cost was evaluated to be too high. Alternative efforts of constructing SOFCs in planar design with metal interconnects were, on the other hand, suffered from poor durability in its early

stage of development. One of plausible reasons for such technological dead-rock seems to be at a point that the target application was stationary so that they aimed at constructing larger flat cells with sealant materials. In such a larger planar stack, temperature distribution developed within planar cells may cause strong mechanical stresses, leading to failure in sealing or to crack formation.

From the mid-1990s, there arose a new wave in fuel cell applications, that is, the automotive application and closely related applications of small stationary. It began with PEFC. Even so, SOFC has also received the impacts of new applications. This leads to two important efforts on SOFC developments: (1) severer requirements for mechanical stability in automotive applications [22] and (2) smaller stationary application. The former has come from the new application proposed by BMW, Delphi, and Renault to utilize SOFC systems as auxiliary power unit in combustion engine cars. Since BMW and Delphi have cooperated with National Laboratories in their own countries, materials development has been made to improve mechanical instability. Development of simulation technique also helps to improve the stack technologies. The latter case of the small stationary systems gave rise to a big impact in Japan, Australia, Switzerland, and UK where the SOFC cogeneration systems have attracted strong attention.

Current issues of SOFC technologies, namely, reliability/durability and cost appear in different manners in respective applications which have different historical background.

This entry is organized as follows: In section "Historical Aspects of Reliability, Durability and Cost Issues," historical aspects are first described to provide essential points of SOFC stack/system development. The technological features of the first-generation cells, namely, sealless tubular cells, will be described in comparison with the second- and the third-generation cells in critical technological issues; these are materials selection of interconnect (oxide or metal), sealing scheme, redox issues of nickel cermets, metal support cells, trade-off relation between reliability and performance, and materials chemistry associated with lowering operation temperature. Section "Durability/Reliability of SOFC Systems" describes durability/reliability of SOFC systems. Failures of system operation are first described. Then, failures of stacks and degradation of cell performances are described in detail with focuses on chromium poisoning, nickel sintering, carbon deposition, sulfur poisoning, etc. Results of field tests are also described in relation to reliability. Section "Cost Issues" describes the cost issue and "Future Directions of SOFC development" are given finally in section "Future Directions."

Historical Aspects of Reliability, Durability, and Cost Issues

Materials compatibility is important in construction of SOFCs. Particularly, chemical and mechanical stabilities are crucial in simultaneously optimizing materials, materials processing and stack design. First success has been achieved by Westinghouse Power Corp. (later Siemens Westinghouse Power Corp. and now Siemens Power Generation Corp.) in the 1980s by adopting the first-generation cell materials, the electrochemical deposition technique to fabricate a dense yttria-stabilized zirconia (YSZ) electrolyte film on porous LSM cathode tubes and subsequent Ni anode on the dense YSZ film as described in Fig. 1. This is called sealless tubular cells, because no use of sealing materials is the important key point. The cells exhibit high performance and also long stability; only a small degradation rate of performance (less than 0.1%/1000 h) has been confirmed for more than 70,000 h for the cell level (see Fig. 2) and more than 30,000 h for the system level. Two demerits, however, were pointed out for those cells by Ackermann et al. [15] in Argonne National Laboratory; one is high cost because of the adoption of electrochemical vapor deposition (EVD) technique which utilizes metal chlorides in vacuum vessels, the other one being low-volume power density. Since then, many attempts have been made to overcome these demerits, namely, alternative materials have been investigated, new materials processing methods have been developed, and alternative stack designs have been attempted (Table 1).

In recent years, rapid progress has been made in the development of SOFC cogeneration systems with several kW scale for residential houses [23–26]; its demonstration has been successfully made in real residential circumstances [23]. In such a situation, degradation, durability, and reliability have appeared again

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 1
Sealless tubular cell: (**a**) cell configuration and (**b**) stack configuration (From [13, 14])

as important issues. Now these should be related with cost issues, because it is already well established that the excellent long stability can be achieved with the electrochemical vapor deposition (EVD) technique despite high cost. The most important point is that the low cost has to be obtained at the same time together with high efficiency and long stability.

First Generation Stack: Sealless Tubular Performance as Standard

Westinghouse Power Corp. made a breakthrough by adopting sealless tubular cells after examining several other types of SOFC stack design such as planar cells or segment-in-series cells. This implies that the sealless tubular cells have many advantages against other designs. Actually, after the breakthrough, they succeeded in demonstrating the long-term stability. From the current knowledge of durability of other cells, their success in long-term stability can be ascribed to the following:

1. The electrochemical vapor deposition (EVD) process has been successfully developed as fabricating a dense electrolyte film on porous cathodes and fixing anode nickel particles on the electrolyte plate with YSZ. This provides a nearly ideal microstructure for electrolyte/electrode interfaces.

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 2
Cell performance degradation of (**a**) the first generation sealless tubular cells by Westinghouse (Currently Siemens, From [13, 14]) and (**b**) the second generation planar cells by Sulzer Hexis (Currently Hexis, From [17])

2. Sealing materials are not used. Particularly, this cell is free from silica; silica is one of materials to be carefully treated.
3. Other metals than nickel are not used in anode atmosphere or in air. Alloys (Fe–Cr, Ni–Cr) sometimes caused troubles such as anomalous corrosion. In sealless tubular cells, nickel is used as anode materials and also as cell-to-cell connecting materials. Note that nickel is stable in the fuel atmosphere without forming oxide scale. Furthermore, a small amount of oxygen can be dissolved so that even when oxygen permeates from the air side on nickel in the fuel side, a steady state flow of oxygen can be established across the nickel/$LaCrO_3$-based interconnects. Nickel connection can be made because this is the cathode-support cell. Note that when the anode-support tubular cell is adopted in a similar design, cell-to-cell connection has to be made in the air side, leading to a severer materials problem.
4. Alumina tubes are used for providing air at the bottom of the cathode compartment. This is acted as heat exchanger to remove heats out of cells. This provides an excellent situation for thermal management on larger stacks.

Immediately after the success of sealless tubular cells, one important analysis was made to clarify the technological features by Argonne National Laboratory [15]. Their main conclusions are given as follows:

1. Fabrication cost is too high
2. Power density per unit volume is less

Status of the sealless tubular cells concerning cost, efficiency, and durability can be summarized as shown in Fig. 3a.

After knowing the success of Westinghouse and technological assessments by ANL, many people started to develop various kinds of SOFC stacks to overcome demerits of the sealless tubular cells. Depending on their technological strategies, several different attempts have been made. These can be summarized as follows:

1. Improvement of sealless tubular cells. To improve the volume power density, flatten tube type or delta type designs have been investigated by Siemens (Westinghouse) themselves [27]. To lower the fabrication cost, sintering-wet process has been successfully adopted by TOTO [28], whereas atmospheric plasma spray was adopted by Siemens themselves [27]. These attempts are based on the idea that tubular cells or their modified cells must be superior to other designs.

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Table 1 Comparison in typical materials and fabrication methods among the first-, second-, and third-generation SOFCs

	First	Second	Third
Cathode	LSM	LSCF	LSCF
Electrolyte	YSZ (50 μm)	YSZ (10 μm) Ni ScSZ, LSGM GDC	ScSZ, GDC
Anode	Ni/YSZ	Ni/YSZ, Ni/SSZ, Ni/DGC	Ni
Interconnect	$LaCrO_3$-based $SrTiO_3$-based	Ferritic, Cr-based	Ferritic
Cell to cell connection	Ni	Ferritic	ferritic
Operation temperature	900–1,000°C	750–800°C	500–650°C
Typical fabrication method	EVD, plasma spray	Wet-sintering	Sintering in reducing atmosphere

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 3
Schematic representation of the current status of technology for achieving three targets of fuel cells, namely, efficiency, cost, and durability; (**a**) the first generation SOFC based on Electrochemical vapor deposition technique; (**b**) the second generation SOFC based on anode-support cells with wet-sintering processes; and (**c**) the third generation based on metal support cells

2. Planar design has been recognized as better in achieving the higher power density in an analogous manner to other fuel cells such as PAFC or MCFC. One approach is to adopt the oxide interconnect, the other being the metal interconnects. Only few developers have adopted the oxide interconnect in planar stacks [29, 30]. One technological reason is that sintering of lanthanum chromite–based ceramics is difficult, particularly in air. Another reason is originated from the cost consideration; when rather thick plates of $LaCrO_3$-based interconnects are used in planar cells, the contribution of La to the total material cost becomes quite large [31]. Adoption of metal interconnects becomes important in stack developments probably because of their technological merits [32, 33]; the use of metal inside SOFC stacks is quite useful for better thermal management, and for controlling the mechanical stress, etc. Even so, demerits can be seen in poisoning of cathodes by Cr originated from oxide scale [34], chemical interactions with sealing materials, and also increasing interface resistivity across the oxide scale. In many cases, utilization of metal interconnect is combined with the adoption of anode support cells.
3. There have been also many efforts in improving stack design such as flatten tubes, micro tubes, or honeycomb type cells. This is mainly from the thermo-mechanical considerations. In order to avoid the thermal shock effectively, utilization of materials having low thermal expansion and high thermal diffusivity are highly required; Al_2O_3 and Si_3N_4 can be regarded as one of such materials for high-temperature use. Unfortunately, YSZ exhibits high thermal expansion and low thermal conductivity and there is no good way of improving those inappropriate properties. Thus, the most effective way of overcoming thermal shock is to shorten the thermal diffusion length so as to relax changes in temperature on thermal shocks. For this purpose, micro-tube or honeycomb structures become attractive.
4. Metal support cells are proposed to realize cost reduction from the materials cost and fabrication cost simultaneously. Compared with nickel which is the major component in the anode support cells, the metal support cells aim at using cheaper Fe–Cr alloy as supporting materials [19]. Instead, the fabrication process becomes rather difficult compared with other cell design.

These activities can be summarized as the second or the third generations of SOFCs. These characteristic features are compared with the first generation in fundamental aspects in Fig. 3. Cost and efficiency are expected to be satisfied, whereas durability has not been confirmed yet. Thus, the main issue associated with the second generation becomes the establishment of durability/reliability (Fig. 4).

Oxide Interconnect Versus Metal Interconnect

Interconnect materials are quite important in fabricating SOFC stacks. To meet the chemical and mechanical stability requirements under an oxygen potential gradient, only a few materials have remained; some spinel compounds such as $NiCr_2O_4$ or $CoCr_2O_4$ were tested as interconnects in the early stage of development without success because of their poor materials stability. Remaining materials are $LaCrO_3$-based or $SrTiO_3$-based perovskite oxides. The interconnect materials need to meet two requirements: good electrical conductivity (at the same time, essentially no oxide ion conductivity) and the good gaseous tightness. This can be met by fabricating into dense plates/films. Furthermore, an additional requirement is derived from the mechanical point of view, that is, the thermal expansion coefficient should match with that of YSZ, and the chemical volume expansion due to valence change should be small enough [35].

The technical issues associated with oxide interconnect can be summarized as follows:

1. Establishment of inexpensive fabrication process for making dense films of $LaCrO_3$-based ceramics. This is because the sintering of $LaCrO_3$ in air is quite difficult since the chromium component tends to volatilize during sintering and to subsequently deposit at interparticle necks as Cr_2O_3; This deposited chromia hinders further sintering [10].
2. Thermal expansion coefficient is another issue. The thermal expansion coefficient of non-doped $LaCrO_3$ is small compared with YSZ. To match the thermal expansion coefficient, there are two ways: one is the heavy alkaline earth doping up to 30 mol%,

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 4
Schematic representation of the materials and associated degradation issues (**a**) the first-generation cells and (**b**) the second-generation cells

the other being addition of alumina to YSZ to reduce the effective thermal expansion coefficient of a mixture of YSZ and Al_2O_3 [35]. This makes it possible to adopt the low concentration (about 10%) doping of alkaline earth.

3. The high electrical conductivity is achieved by holes created as a result of doping of alkali earth oxide; however, in reducing atmosphere, hole and Cr^{4+} is reduced to Cr^{3+} and oxide ion vacancies. This valence change gives rise to the volume expansion,

which is called the chemical volume expansion [7]. For the heavily doped system, this chemical volume expansion is too big so that additional B-site doping is necessarily made to reduce the chemical volume expansion.

4. The material cost of lanthanum is high so that the thickness of the oxide interconnects should be thin enough to reduce the amount used in cells [31]. On the other hand, the $LaCrO_3$-based interconnects should be thick enough to prevent the electrochemical oxygen permeation which takes place as the bipolar diffusion of oxide ions and holes inside the interconnect. For such a purpose, Ca-doped $LaCrO_3$ is not appropriate because those ceramics are highest in gas permeation among the alkali earth-doped $LaCrO_3$ [36, 37].
5. For the $SrTiO_3$-based interconnects, sintering is much easier than $LaCrO_3$-based ceramics, whereas the electrical properties are not good, particularly in the air side [38].

When the metal interconnects are adopted in the second generation stack, there arise other technical issues:

1. Metal interconnects typically made of ferritic alloys have slightly higher thermal expansion coefficients than YSZ. A new alloy was produced so as to fit the thermal expansion of YSZ; this is a Cr-based alloy, $Cr5Fe1Y_2O_3$ [39]. Since this alloy is oxide dispersed and therefore quite hard, it is not easy to fabricate it into a desired shape. For this purpose, powder metallurgy process has been developed [40].
2. Most important difference of metal interconnects from oxide interconnects is that such alloys will be oxidized during the cell operation. This inevitably involves kinetic aspects in durability of materials. The most important aspect related with durability is materials behavior under a steep oxygen potential gradient. Electrolyte and interconnect materials should be stable under such a gradient. In addition, alloys have to be stable on both sides of materials, namely, the air side as well as the fuel side, because the oxygen potential inside normal Fe–Cr alloys is maintained to be quite low compared with the fuel atmosphere. One difference from oxide interconnect is that oxygen atoms to be transferred inside oxide interconnects will permeate through the interconnect plate, whereas oxygen atoms reacted with or dissolved into alloys do not permeate but will be accumulated in the surface area to form oxide scale. This increasing amount of oxide scales with operational time becomes an important factor of limiting life time. Note here that in the first-generation sealless tubular cells, only nickel is used in the fuel compartment and such nickel is oxygen permeable when oxygen flux is low enough to maintain the reducing condition.
3. Immediately after starting the utilization of metal interconnects, the chromium poisoning for lanthanum manganite–based cathode was recognized as a severe degradation [34, 41–43]. The Cr_2O_3 component of the oxide scales reacts with oxygen molecule in air with/without water vapor to emit the vapors of $CrO_3(g)$ or $CrO_2(OH)_2(g)$. Such vapors come to the electrochemically active sites of LSM cathode (namely, three phase boundaries) and deposited as Cr_2O_3 or $MnCr_2O_4$. Although detailed mechanism is different, similar poisoning effects due to Cr vapors were found for other cathodes such as LSCF through the $SrCrO_4$ formation.
4. A most effective way of overcoming Cr poisoning is to reduce Cr vapors from oxide scales [44]. As a result, coating technique becomes crucial in the utilization of metal interconnect. Materials to be coated should meet several requirements concerning the stability under a steep oxygen potential gradient. Such requirements are quite similar to those for the oxide interconnects. Thus, perovskite oxides have been tested as coating materials [45]. As far as the cation diffusivity and the oxygen permeability are concerned, the lanthanum chromite–based materials will be most appropriate. Even so, the fabrication technique to form a dense film on alloys is quite limited. Attempts have been made to try to utilize other perovskite materials such as cobaltites and manganites. Since those perovskites are oxygen permeable, oxide scales should grow under the coating materials. In addition to Cr_2O_3, some spinel phases are formed between the alloys and the coating. Investigations on such complicated oxide layers lead to selection of $MnCo_2O_4$ spinels as coating materials [46].
5. From the viewpoint of cost, utilization of metal interconnects should be considered as the combined

technology with coating. Although raw alloy materials are cheaper than lanthanum, the fabrication cost will increase due to the sophisticated coating technique. If coating cannot be avoided, it is essential to reduce the fabrication cost for coating as well as to reduce further the raw materials cost because the development of mother alloys alone cannot lead to low cost enough as interconnects.

From the materials design point of view for those electrical conductive oxides which are stable under an oxygen potential gradient, oxide interconnects and coating materials for alloys are quite similar. From the fabrication method, however, there are several differences. Inexpensive sintering process can be applied for oxide interconnects, whereas high-temperature heat treatment is limited for coating. The low-pressure plasma splay technique was successfully adopted to form dense films; however, from the cost point of view, this is not appropriate. The atmospheric pressure plasma splay is more cost effective, but the quality of fabricated films is not excellent.

Seals

Seal technology is quite sophisticated among the stacking technologies. As described above, the first success of stacking SOFCs by Westinghouse has been made by adopting the sealless design combined with the electrochemical vapor deposition technique. This clearly indicates that when seals are adopted, there arise many materials problems and without solving those problems, any stacks cannot survive.

The most severe requirements for sealing materials are

1. Appropriate bonding to prevent gaseous leakage. Compared with PEFC which can be easily sealed gas-tightly by just compressing the main cell components, it is impossible for SOFC to achieve the gas-tightness among the ceramic cell components without activation in the atomic level.
2. Sometimes, not quite often, sealing can be achieved by co-sintering two materials to be joined at a relatively high temperature. This can be regarded as a thermally activated process at interfaces.
3. In many cases, glasses or crystallized glasses will be used as sealing materials. This is because glasses are convenient for achieving the gas-tightness due to their deformable nature. Even so, glasses are non-stable materials and tend to undergo the transformation into crystalline phases on reactions with other cell components. This changes the mechanical property or the gas permeability at the bonding places. Such processes are dependent on various factors; temperature, reaction rate, crystallization rate, etc. This implies that their mechanical strength depends on their thermal history. Since there is a large temperature distribution among the places where sealing is needed, deterioration of sealed parts takes place in a different manner from place to place. Note that the durability/reliability of stacks is determined by the weakest place.
4. When no glasses will be used and compression sealing [47] will be adopted, complete gas tightness cannot be necessarily achieved. Thus effects due to gas leakage will appear in various aspects of stack behavior. Since the SOFC stacks consist of the oxide ion conductive and/or electronic conductive materials, local gas leakage gives rise to those effects which will be spread throughout the stack [48]. In this sense, to make an analysis on gas leakage and to overcome this issue, it will be needed to understand a whole behavior of stacks.

In view of these features, sealing is not the localized materials issue but it is a matter of whole stacks. In this sense, the characteristic features of the adopted stack design and the sequential of fabrication depends on the way of making seals.

Redox Issues

In a typical case, the stack fabrication will be completed by reducing NiO to Ni metal to form the electrical path in the anode side. On this reduction, the sintered NiO will be reduced by hydrogen to become nickel powders first and then to make an electrical path after some coagulation; during this process, the mechanical constrains introduced at the high temperature heat treatment will be released at the anode side and a new constrained state will start under the oxygen potential gradient [49].

When the sealless structure is adopted and the remaining fuels are combusted inside the stack, there is always some possibility that combusted gases

will diffuse backward to the nickel anode area and will reoxidize nickel.

For anode support cells, one needs to have an appropriate method of sealing edges of cells where the porous supporting anode should be appropriately closed. The flatten tubes provide one good way of sealing sides by high-temperature sintering without using seals.

For small power-unit systems such as the SOFC cogeneration systems for the residential applications, usually no purge gas will be used. Thus, there arises a big possibility that the anodes can be reoxidized during the start-up and shutdown cycles.

Metal Support Cells

The metal support cells can be regarded as the third generation. The major driving forces for making the metal support cells can be summarized as follows;

1. For the mobile/transportation application, it is highly required to start up rapidly, to make stacks mechanically strong enough against mechanical or thermal shocks. For this purpose, ANL adopted the metal-supported cells and they made attempts of fabricating metal parts in essentially the same manner as those for ceramics, that is, they tested to fabricate by sintering metal powders in the reducing atmosphere [18].
2 Another major driving force for metal support cells is cost reduction [19]. For the anode-supported cells, a relatively large amount of nickel will be used because the nickel cermet becomes the major structural supporting component. To achieve a drastic change in row materials cost, therefore, cheaper alloys should be used as the major component. Note also that from the raw materials point of view, ceramics are more expensive than metals in general.
3. The use of metal as supporting component implies that the operational temperature will be below 800°C which is the typical operational temperature for the second-generation cells. At such a low temperature, brazing will be used instead of glass-based sealing methods. This will make materials chemistry much simpler.

Despite expected low cost, it is expected that the fabrication technology is much more difficult for metal support cells. This is illustrated in Fig. 3c.

Reliability Versus Performance and Its Relation to Operation Temperature

Utilization of metal interconnects requires lower temperature operation, and this low operation temperature is generally expected to lead to less severe conditions for degradations because of the Arrhenius-type behavior of processes involved in degradations. Accumulated knowledge on durability, however, exhibits an interesting feature that on contrary to this expectation, some degradations become more severe at lower temperatures. That is because with lowering operation temperature, there arise an increasing number of factors affecting durability as indicated as follows:

1. In order to achieve the same performance as the first generation, the more active electrodes are needed. In particular, cathode performance exhibit rather large temperature dependence [50]. Thus, instead of the stable LSM cathode, it is needed to utilize more active cathodes such as LSCF. The electrode activity of LSCF is high because this material exhibits ionic and electronic mixed conductivity and also shows high surface reaction rate for the oxygen incorporation reaction. These features are originated from the high concentration of oxide ion vacancies in LSCF. This is chemically represented as follows: the $SrFeO_3$ or $SrCoO_3$ components in perovskite are reduced to form Fe^{3+}/Co^{+3} ions together with the oxide ion vacancies. Chemically speaking, the oxide ion vacancy formation is due to the fact that unstable $SrFeO_3$ is reduced to be $SrFeO_{3-x}$ and $O_2(g)$. In other words, the valence stability of Fe^{4+}/Co^{+4} is weak compared with that of Mn^{4+} in the perovskite lattice.
2. This in turn indicates that LSCF is also reactive to other materials/gases; typical reactions are those with YSZ to form zirconates ($SrZrO_4$ or $La_2Zr_2O_7$) and with chromium containing vapors($CrO_3(g)$ or $CrO_2(OH)_2$) to form $SrCrO_4$. In this reaction, the $SrFeO_{3-x}$ component is reductively decomposed into SrO in $SrZrO_4/SrCrO_4$ and $FeO+O_2(g)$. Thus, this chemical reactivity is originated from the same physicochemical properties described above. In this sense, the performance and the durability are in trade-off relation. This is summarized in Table 2 [4, 51].

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Table 2 Comparison of cathodes among lanthanum strontium manganites, ferrites, and cobaltites in their chemical reactivity, functionality as cathode, and tolerance against Cr poisoning

Items	LSM	LSF	LSC
Valence stability	Mn^{4+}Stable	Fe^{4+}unstable	$Co^{4+}Co^{3+}$ unstable
O^{2-}conductive	Nearly zero	High	High
Cathode mechanism	Three phase boundaries	Two phase boundaries (surface)	
Reactivity with YSZ	Stable (A-site deficient)	$SrZrO_3$ formation	$La_2Zr_2O_7$ $SrZrO_3$ formation
Reactivity with Cr	Cr^{3+} substitute	$SrCrO_4/Cr^{3+}$ substitution	$SrCrO_4/Cr^{3+}$ Cr^{4+} substitution
Cr poisoning	Significant	Not seen in early stage but causes various deteriorations	

3. Instead of stable YSZ, use is frequently made of other electrolytes showing higher oxide-ion conductivity; these are ScSZ (Scandia-stabilized zirconia), GDC (gadolinia-doped ceria), and LSGM (lanthanum strontium gallium magnesium oxide). The chemical reactivity of these electrolytes is, however, higher than YSZ. In many cases, ceria is thought to be more stable than zirconia. This is true when comparison is made just between ceria and zirconia. However, when comparison is made among the dopants, this is not the case; dopants in ceria are not well stabilized so that they are more reactive than yttria in YSZ [52].
4. Use of metal interconnect gives rise to a new situation that materials are not necessarily used in their most stable states. This means that the durability is determined not only by equilibrium properties but also by kinetic properties. Thus, corrosion becomes one of the main issues at lower temperatures.
5. The equilibrium properties tend to shift to a more reactive side with decreasing temperature [52]. In particular, those reactions which involve the condensation of the gaseous component become more favored at lower operation temperatures. A typical example is the adsorption of sulfur from H_2S gases on nickel. Another important example is the redox reactions which emit or adsorb oxygen gas. At low temperatures, the oxidation becomes thermodynamically favored. Those reactions with gaseous impurities (including water vapor, CO_2) exhibit the same tendency. With decreasing temperature, the driving force for such reaction increases due to the negative entropy effect. Those features are shown as the oxygen potential vs. temperature plot in Fig. 5.
6. From the Arrhenius behavior of kinetic processes, the reaction rate decreases exponentially at low temperatures. This in turn gives rise to larger driving force for degradation. For example, the overpotential of LSM cathode increases with decreasing temperature as expected. This is understandable from the Arrhenius behavior. This larger overpotential at lower temperatures promotes Cr poisoning because the oxygen potential difference corresponding to the overpotential assists the Cr vapor to reach the electrochemically active sites at the three-phase boundaries (TPBs) and to be electrochemically reduced to form Cr_2O_3 (see Fig. 6). In another example using the samarium strontium cobaltite (SSC) cathode, reactions with SO_2 proceed fast at a high temperature so that only a small amount of SO_2 can reach the electrochemically active zone. With decreasing temperature, however, this trapping ability is weakened; as a result, a larger amount of SO_2 can attack the sites, leading to faster degradation compared with high temperature [53, 54]. These examples indicate that one degradation phenomenon consists of several processes which have their own temperature dependence. Thus, the apparent degradation rate becomes fast at lower temperatures.
7. So-called inert metals such as Pt and Ag are not necessarily chemically inert at lower temperatures [55].

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 5

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 6
Temperature dependence of cathode degradation (**a**) Cr poisoning on LSM cathodes (From [34]) (**b**) SO_2 poisoning on SSC cathode (From [53])

8. For active cathodes, an interlayer is inserted between such cathodes and the YSZ electrolyte to prevent chemical reactions, leading to a complicated interconnect/electrode/electrolyte structure. This introduces another technical requirement for fabricating those layers durable enough.

9. Effects of impurities may appear in a more significant manner at low temperatures. One example is sintering of nickel at low temperatures. Compared with the first-generation cells, there are many reports suggesting more significant sintering in the second-generation cells [56]. This is probably

due to gaseous impurities which tend to condensate at low temperatures.

10. With decreasing temperature, nature of electrochemical reactions may change. Particularly, degradation may depend not only on the major electrochemical reactions but also on the secondary reactions. For example, protons in YSZ or GDC do not contribute to the major electrochemical reaction because of its extremely low transport number. However, it is not adequate to neglect completely possible effects of protons in electrolytes or in cathodes. In particular, GDC exhibits two-orders-of-magnitude higher proton solubility than YSZ [57, 58]. This makes it reasonable to assume that protons can contribute to side electrochemical reactions.

When consideration is made on chemical compatibility of cathodes with other components/impurities, it becomes clear that the selection of elements in the major components is critically important. Differences between LSM, LSC, LSF, and LSCF are originated mainly from the thermodynamic activity of SrO component in coexistence with transition metal oxides. Thus, no use of the SrO component in cathodes can be good attempts of avoiding gap between the stability and the performance. Actually, LNF ($La(Ni,Fe)O_3$) proposed by NTT [59] seems to indicate some progress in this issue.

Durability/Reliability of SOFC Systems

Failures in Flow Systems

The SOFC system is an energy converter from fuels as chemical energy to electricity and heats. There are four flows inside stacks, namely, fuel flow, air flow, electrical flow, and heat flow. In order to maintain the proper function as energy converter, these four flows have to be well maintained and controlled so as to harmonize to generate electricity and remove heats [60].

SOFC systems frequently have to be stopped in their operation due to unexpected failures in controlling systematic flows of fuels, water to be used in reforming, air, or electricity. Typical examples are given as follows:

1. Air flow: When air blower malfunctions, systems will be in trouble. Oxygen starvation takes place in cathodes. Perovskite oxide cathodes will be reduced to provide oxygen if oxygen gas is not sufficiently available. As a result, such cathodes are heavily damaged.
2. Fuel and fuel treatment: Except for hydrogen gas, normal fuels need to be reformed before utilization. The water reforming needs to add water to hydrocarbons; when water is not supplied in a proper amount, carbon deposition will take place. Deposited carbon can act as catalyst for further carbon deposition, leading to collapse of fuel flow. Similarly, when an amount of air for partial oxidation or autothermal oxidation is not well controlled, essentially the same situation can be reproduced. When fuel supply is stopped accidentally, fuel starvation takes place and nickel anodes will be oxidized by water vapors.
3. Concerning the electrical path, there can be two failure modes: one is shorting, the other being cut-off of path. When shorting will start, the current should pass until generated electrical potential is cancelled out with the ohmic loss in the shorting circuit path; typically, this happens when one of the chemicals (fuel or oxygen) becomes empty. A large current will be concentrated in a limited area, leading to damage in local area. The latter case of cut-off corresponds to the so-called death of the electrochemical cells. This will happen on the electrochemical sites or along the path.
4. Heats are by-products of the electrochemical conversion and therefore have to be removed effectively. Usually this removal of heats is made with the air flow which is supplied in an excess amount to the stoichiometrically required one. When this removal becomes insufficient, the temperature will increase and enhance various kinds of activation processes. The contribution of radiation loss from the stack surface will increase; in other words, temperature distribution inside stacks becomes large.

These failures should be avoided by well-designed and well-trained control systems.

Field Tests

Field tests of the SOFC systems have been made in several places. In Germany, field test was initiated by the utility companies. Among them, the test on the

Sulzer Hexis system has been made in recent years and well documented in the literature [17]. After the field test, Sulzer Hexis made improvements on the system configurations; these seem to be interesting in knowing what kinds of materials issues were involved. First to be considered is the effect of sulfur. Those SOFC systems in Europe are designed to be utilized with natural gases available from natural gas pipelines. This implies that the sulfur content is rather high and changeable. They chose to operate at a higher temperature instead of applying the desulfurization process. As a result, their cells with Cr-base alloys are operated at around 900°C. Another issue was $CaSO_4$. To avoid the contamination by $CaSO_4$, they decided not to use the external water.

In Japan, a demonstration program for the SOFC cogeneration systems for residential houses has been initiated for the period 2007–2010. Kyocera reported the statistics of troubles during the demonstration program [61, 62]; this is summarized in Fig. 7. Troubles in systems were well treated to be improved so that a number of troubles decrease year by year.

Failures/Degradation in SOFC Stacks

Since there are many kinds of SOFC stacks which are fabricated by different fabrication methods in different sequences, it looks rather hard to describe the failure/degradation modes of stacks in a proper manner. Even so, it seems possible to extract some common features out of various failure/degradation modes.

Long-Term Operation During a long period of operation time, some changes may happen on the following aspects:

1. Deformation due to creep when cells are stacked into a tower consisting of a large number of cells.
2. Change in microstructure and related electrode structure due to diffusion in the vicinity of active sites.
3. Change in mechanical strength due to surface segregation, other aging effects or impurities effects.
4. Those changes in small parts may cause accumulated effects on the durability against thermal shocks or mechanical shocks.

Driving forces for such phenomena are diffusion in solid materials and reactions of solid components with gaseous components. These effects are expected to determine the life time beyond 10,000 h.

These features have been found to be highly correlated with the fabrication method/sequence as well as materials selected. For example, anode support cells have stable anodes but there remain several points to be optimized for a cathode-complex-layer structure.

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 7
Summary of troubles during the field test for the 2007 fiscal year's SOFC units. These are categorized into troubles in Control system, heat recovery system, water treatment system air supply system, reformer, and cell stack itself (From [61])

On contrary, cathode-support cells have the stable performance for cathodes, but anodes may have some changed in microstructure because of nickel sintering [63].

Failures Originating from Thermal Cycles or Redox Cycles The SOFC stacks consist all of solid materials. Except for nickel anode and metal interconnects, all other materials are ceramics so that the mechanical instability during thermal cycles and redox cycles can be one of possible failures.

In many cases, failures are associated with stress concentration during thermal cycles or redox cycles. Mechanical stresses are closely related with volume changes of one component leading to mismatch along interfaces.

Volume changes are ascribed to

1. Thermal expansion
2. Chemical volume change due to valence change within the same crystal lattice
3. Redox of the main component such as Ni
4. Precipitation of new phases at interfaces or bonded regions

During operation, temperature distribution can be determined by the current density distribution and related heat release from the surface. This implies that the thermal stress can be properly treated only by the combined analyses on electrochemical performance, gaseous concentration, and thermal conduction. When stacks will be cooled down, temperature distribution can be determined by cooling mechanism so that the thermal stress distribution may change from those under operation.

Effects Appearing in Stacks

1. Edge effect: Small changes in the shape of repeating elements may be accumulated and appear as an edge effect. In many cases, ceramic cells have their own structure to keep the electrical path and gaseous tightness inside stacks. During a long-term operation or frequent thermal cycles, deformation can appear as a sum of the accumulated small changes in shape. In this sense, edges tend to have troubles in loss of the electrical loss, gaseous tightness, etc. In addition, temperature gradient tends to be steep in the vicinity of edges. As a result, degradation is apparently worsened in edge parts.
2. Effect of stack weight: When the horizontal cells are vertically stacked to form tower stacks/modules, an effect of gravitational weight may appear at the bottom of the stacks. This is a similar situation to the stacks of MCFC where a large number of horizontal cells are stacked and the effect of creep will appear when the selection of anode materials is not appropriate, for example, copper is recognized as such materials. For the SOFC stacks, no report has been made on creep behavior of the nickel cermet anodes so far. Ferritic steels are recognized as weaker against creep than austenite steels.
3. Gas distribution: Gas manifold system is critically important in the stack technology. When this malfunctions, supplying rate of gases become different from cell to cell, whereas the same electrical current passes through such cells connected in series. As a result, there can be a shortage of fuels in a particular cell, leading to damage of the cell [64].
4. Distribution of current: The SOFC stacks consist of highly electronic conductive electrodes and of highly ionic conductive electrolyte so that the current distribution can be easily reestablished when some parts in flows of fuel or air becomes ineffective or some parts of electrode area are damaged [65]. This electrochemical response to degradation makes it difficult to find out symptom of deteriorated parts while such deterioration continues to take place. In many cases, the degradation of stack performance appears to be linear with operation time.
5. Contamination: The only one appropriate method for investigating on the significance of contamination from other components and on plausible effects on electrode reactivity, electrical resistivity, or gaseous permeability is utilization of secondary ion mass spectrometry (SIMS) [66, 67]. Attempts by AIST clarified the interesting behavior of elements inside the SOFC stacks [68] as shown in Fig. 8.
   (a) Impurities are common in many cases. For example, sodium is quite frequently observed contaminant, whereas potassium is much less than sodium. In addition, aluminum and silicon are also always detected; frequently, but not always, phosphor is detected. Sulfur is also found to be a frequently observed contaminant.

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 8
Impurities in anodes for four SOFC stacks with different materials and designs. Impurities were determined with SIMS on the 24 h operation and on the longer (about 5,000 h) operations. (**a**) High-temperature segment-in-series cell by MHI, (**b**) intermediate flatten tubular cell by Kyocera, (**c**) high temperature sealless tubular cells by TOTO, and (**d**) intermediate temperature disk-type planar cells by Mitsubishi Materials corp

This is not necessarily derived from fuels. Even in air side, sulfur can be detected. Halogen such as Cl and F can also be detected. Note that Se, As, and Sb are not detected although those elements are major impurities in coal-derived gases.

(b) Impurity levels however depend on stacks/systems. For example, the Na contamination depends largely on raw materials or on the fabrication process.

(c) There are several elements which increase in concentration during a long-term operation. Apparently, such elements are transported as the gaseous species in fuel or air atmospheres. Generally speaking, contamination is much severer in the fuel side compared with the air side. This is due to the presence of water vapors in fuel sides, enhancing the volatilization by forming metal hydroxide vapors or metal suboxide vapors. Actually, the contamination level is higher in many cases in the downstream where water vapors are increased.

(d) Some particular elements are deposited on electrodes. Those elements which are known as poisons for the electrode activity, for example, chromium in cathode and phosphor in anode, are detected in a more concentrated manner at the three-phase boundaries where the main electrochemical reactions take place.

(e) Sources of contaminants can be suggested as follows: thermal insulating materials, alloys, sealing materials, if any.

6. Behavior during emergency stop: Many durability tests have suffered from emergency stops which are caused, for example, by failures of controlling system for the test facilities. Such accidental stop tends to cause changes in performance or mechanical failure. Severest situation is rapid cooling with the purge gases which will be introduced mandatorily, leading to mechanical failure or heavy damage of cells [69].

Anomalous Situation

1. Gaseous leakage: Anomalous gaseous leakage can take place as a result of crack formation of electrolyte, interconnect, or seals. In addition, oxygen can be permeable through the oxide electrolyte/interconnect in a form of bipolar diffusion of oxide ion and electrons. In any case, gaseous leakage gives rise to combustion without generating electricity. This releases heats locally at the place where combustion occurs. This may provide a local hot spot of electrolyte/interconnect. Since gaseous leakage tends to increase with temperature, local heating enhances further gaseous leakage regardless of leakage through pores/cracks or electrochemical oxygen permeation.
2. Shorting: When electrical shorting takes place, current will pass within the shorting circuit until fuel/air becomes in shortage and as a result, high resistive materials are formed on the electrical path. Current density is determined so as to cancel out electromotive force by the overpotential and ohmic loss inside shortened circuit. Unlike the electrochemical oxygen permeation, electrons move quite fast. Therefore, combustion rate and heat generation rate are fast. Since the ionic conductivity and the electrode activity are higher at higher temperatures, consumption rate increases until there is shortage of fuel or air.
3. Back diffusion of combusted gases: Some stacks are designed not to have sealing parts. In such a case, combustion of remaining fuels takes place just outside the electricity-generating cell area. In other words, there is a great possibility that the combusted gas will diffuse backward to the electrode area. To protect particularly nickels against such an oxidative atmosphere, an appropriate distance should be maintained between combusting area and the electrochemical active area.

Redistribution of Current Flow Among Cells Connected in Parallel or Series

When a cell or a part of a cell is degraded, this should appear as change in cell performances. When the electrical potential decrease takes place in one cell among cells connected in series, it can be detected easily by watching the respective cell performance. On the other hand, when there are many other cells which are connected in parallel with a degraded cell, the current redistribution takes place so as to minimize effects of degraded cells. In such a case, it becomes difficult to detect those degradations from changes in cell performance alone.

Degradation in Cell Performance

Cell performance is degraded from various reasons. Some degradations are caused from the main components of fuel, others being from contaminants. In many cases, operation temperature plays an important role, whereas the overpotential can become the major factor of controlling degradation. First of all, the places causing potential drops are listed and their relation to other operation conditions is described in section "Operation Conditions and Their Relations to Degradation of Repeat Elements" and then respective poisoning effects will be described.

Operation Conditions and Their Relations to Degradation of Repeat Elements

1. Exothermic and Endothermic Effects

   Figure 9 summarizes schematically those places where exothermic or endothermic processes take place in repeated elements.

   (a) Most important heat effects are the exothermic process due to the electrochemical reaction at the active reaction sites. This contribution increases with increasing temperature. This is due to the reversible reaction so that this effect cannot be detected in AC impedance spectroscopic measurements under OCV conditions; the exothermal and endothermic effects are cancelled out in AC. This effect can appear in the DC polarization measurements; with increasing current density, exothermic heats increase, leading to local heating in the vicinity of the active sites.

   (b) Potential drop due to the electrode overpotential appear also in the electrochemical active sites. This is however irreversible.

   (c) Ohmic loss is also irreversible but appearing along the electrical path with low conductivity.

   (d) Interface resistivity: between cells and interconnects or at cell-to-cell connection potential drop can arise.

(e) Oxygen permeation, if any, results in local heating due to combustion without generating electricity.
(f) For internal reforming inside anode layers, local cooling takes place at those places where reforming reactions proceed.

2. Effects of current density

In addition to temperature, there are several operational variables which should be examined carefully in their relations to degradation. One of such variables is the current density. In what follows, plausible effects of increasing current density will be examined in two levels: cell level and stack level.

In cell level:

(a) With increasing current density, heats are emitted at the electrochemical active sites, therefore, temperature at the active sites increases.
(b) With increasing current density, the overpotential around the active sites increases. When the overpotential is the driving force, degradation should be given as a function of overpotential as will be shown in Cr poisoning for LSM cathodes.
(c) When the oxygen potential at the active sites plays an important role in determining the equilibrium for a particular degradation, it can be related to the current density in an indirect way.
(d) With increasing current density, gaseous flow rates for air and fuel increase if the utilization of air or fuel is kept constant. When poisons for electrode activities are carried with air or fuels, increasing flow rates implies that an amount of transported poisons increases at active sites.

In stacks level:

(a) Since the conversion efficiency decreases with increasing current density, heats to be removed increase in two aspects: (1) Reversible heats increase linearly with current density and (2) Irreversible heats increase nonlinearly under the same fuel utilization.
(b) Thermal balance will be achieved (1) when air flow rate increases resulting in lower air utilization or (2) when a larger temperature distribution is allowed to have the larger heat exchange with the same amount of gas flow.

For the latter case, the maximum cell temperature should be increased.

3. Oxygen Potential

Another important variable related with the operation condition is oxygen potential.

When the degradation of electrode performance is considered, the oxygen potential distribution inside electrode layer or at the electrode/electrolyte interfaces becomes important. In particular, the oxygen potential at the electrochemical reaction sites is critical.

Furthermore, oxygen potential distribution may change during operations. Typical examples are schematically shown in Fig. 10. for the oxygen potential ($\mu(O_2)$) distribution in relation to electron electrochemical potential ($\eta(e^-)$) and oxide-ion electrical potential ($\mu(O^{2-})$)and are summarized as follows:

(a) Normal cases: the electrode overpotential corresponds to a drop of the oxygen potential at the active sites. In cathodes, the overpotential can be interpreted in terms of the oxygen atom diffusion potential on the LSM surface, whereas the oxygen potential drop should appear across the surface of active LSCF cathodes. For nickel anodes, the oxygen potential drop corresponds to the diffusion of hydrogen atoms on nickel. Even when there is a distribution of electrode activity or gaseous concentration inside one cell, the oxygen potential at the active sites is controlled to provide the same electrical potential throughout the cell.

(b) Fuel/air starvation. Oxygen potential in the starvation side changes drastically from the normal oxygen potential. As a result, some damage may occur on the electrode. In such a case, nickel can be oxidized while LSCF cathodes can be partially decomposed, when the oxygen potential changes beyond the thermodynamic limit.

(c) Degradation of one electrode of a cell among in-series connected cells. In a series connection, the same current passes through all cells in the

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 10

Typical changes in electrical potential, oxygen potential and oxide ion electrochemical potential for (1) OCV, (2) normal operation, (3) normal operation with thicker electrolyte, and (4) cathode damaged cell and weakest cell on shorting cells in series

series. When one electrode is degraded, the overpotential increases under the same current density. The generating voltage decreases. Even when a damaged cell cannot generate the electricity, the current is mandatorily passed through the cell. In such a case, the oxygen potential at the electrode/electrolyte interface is shifted to an extremely oxidative/reductive side.

(d) Short circuit with/without outer resistance. When shorting takes place among in-series connected cells, a large amount of current may pass through to cancel out the generated voltage with the resistivity/overpotential of damaged cells. At the beginning, the current is limited by the gas diffusion of air or fuels. Once there appears difference in cell performance including gas diffusion, the generated voltage tends to be cancelled out with the electrode resistivity or gas diffusion resistivity of a particular damaged cell. This suggests that heats are generated locally at the damaged cells. Since the Ohmic loss inside the electrolyte and other places are essentially the same between the damaged and the normal cells, a drastic difference should appear as electrode resistivity. When there are differences in electrode activities among the damaged cells, the current tends to be concentrated in an area with better electrode activity. This will continue to a situation where air or fuel will be in starvation in a major part of cells, leading to lowering in generated voltage.

Chromium Poisoning Chromium poisoning was first observed during the investigation of utilization of metal interconnect at a rather high temperature like 900°C together with LSM cathodes. Therefore many investigations [34, 70–76] have been made on the chromium poisoning effects of lanthanum strontium manganite cathodes. Among them, the work by Taniguchi et al. [34] is excellent in a sense that from a large number of experimental results obtained by changing cathode materials and testing conditions such as temperature, etc., they eventually found an interesting fact that the half-life time of any manganite cathodes is governed by a simple quantity, namely, log a(O), derived directly from the overpotential of the cathodes with a conversion factor of $4F/2.303\ RT$. This is well interpreted in terms of the cathode reaction model for the lanthanum strontium manganites [77]; essentially no oxide ion conduction is available in LSM. TPBs become only electrochemically active sites and, as a result, there arises a large oxygen potential gradient in the TPB vicinity which in turn provides a driving force for chromium-containing vapors to attack the electrochemical sites. In an actual segment-in-series cell, the chromium concentration at TPBs was observed by using SIMS technique [68] (see Fig. 11). The observed change in an accumulated amount of chromium was found to have excellent correlation with the cell performance degradation. That is, degradation in a level of several percent in operating potential is caused by the chromium accumulated at TPBs in the order of several hundred parts per million. This strongly suggests that without measuring with SIMS, no proper examination can be made on a long life time of LSM cathodes in an order of several ten thousand hours.

Another interesting finding is obtained by Matsuzaki and Yasuda [69] – they found that the chromium poisoning depends not only on cathode materials but also on electrolyte to be used with cathodes. From four possible combinations made with LSM and LSCF as cathode and YSZ and SDC as electrolyte, they found that the LSCF/SDC combination does not show any degradation under the same conditions. Since then, many efforts have been made on the non-LSM cathode/ceria interlayer/YSZ systems [78, 79]. In some cases, cell performance is linearly degraded from beginning, whereas the performance is not directly related with the $SrCrO_4$ formation which is always observed. From analyses on the chemical stability of cathodes and their electrode reaction mechanism based on the mixed conductivity, the generalized degradation mechanism [42, 51] can be derived to cover phenomena occurring at the chemical reactions sites as well as the electrochemically active sites. The important physicochemical feature is the probability of poisoning substances arriving at the sites by penetrating though a trapping zone.

Lanthanum nickel-iron oxide cathodes, $La(Ni,Fe)O_3$, have attracted much attention because they show essentially no effects of chromium poisoning [59]. This is mainly because there is no chance of $SrCrO_4$ formation. From the thermodynamic point of view, there is

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 11
(**a**) The time-dependent degradation of segment-in-series cells by Mitsubishi heavy industry. (**b**) Correlation of electrode reaction resistivity and the amount of accumulated chromium at the three phase boundaries

a possibility that the $La(Ni,Fe)O_3$ perovskites react with chromium-containing vapors to form the $La(Ni,Fe,Cr)O_3$ solid solution [42]. Even so, such perovskites must still be electro-conductive, although some surface kinetic activity will be lowered due to the fact that lanthanum chromite has lower catalytic activity among the transition metal perovskite oxides.

In recent years, an interesting but troublesome fact has been revealed, that is, Pt wire reacts with oxygen in air to form $PtO_2(g)$ and will be deposited on the three phase boundaries of LSM cathodes [80]. Usually, Pt cathodes are not better than perovskite cathodes so that the electrode activity may be lowered when such Pt will be deposited on cathodes. However, the situation for the chromium poisoning for the LSM cathode is quite different. When Pt is deposited on TPB of LSM cathodes, the cathode performance can be improved or lowered depending on the state of deposited Pt. This disturbs the effects of chromium on the LSM cathodes. This makes it difficult to examine the chromium poisoning in a laboratory scale.

Other effects such as potassium are reported [81]. The most recent trend to prevent Cr poisoning is to reduce the chromium volatilization from alloys [82]. This is related to the interconnect issues.

Nickel Sintering Since the EVD nickel anode is fabricated so as to be firmly fixed to the YSZ electrolyte, the degradation rate of such electrode is small. Compared with the EVD nickel anode, normal Nickel

cermet anodes are fabricated by sintering after slurry coating. This implies that the mechanical strength between YSZ and nickel is not necessarily good enough so that pre-annealing process is needed to have a good contact.

For the first-generation cells to be operated at 900–1,000°C, sintering of nickel appears as a result of bulk diffusion based on the normal thermal activation process; note that the melting temperature of nickel is 1,728 K and therefore above two thirds of melting temperature, i.e., 1,152 K = 880°C, sintering can be significant. Actually, experimental observation indicates the change in microstructure in the range of several thousand hours due to sintering.

For the second-generation cells to be operated at 800°C or below, sintering exhibits more complicated features. Sintering depends largely on stacks or cells. This implies that the fabrication as well as operation conditions may affect sintering.

About the operation condition, details of nickel electrode degradation have been investigated by Karlsruhe Institute of technology group [83, 84]; they changed the fuel composition and current density separately with a parameter of operating potential and found that the degradation is severe with increasing water content in fuel and with increasing current density (see Fig. 12). Although there is no examination on relation between such degradation and sintering, this seems to be due to sintering. In a cell test, Topsøe Fuel Cells reported that the degradation of nickel anode is severe in the region where the fuel utilization is high, and correspondingly they observed actual sintering of nickel [56].

An interesting feature associated with sintering is that it can take place on thermal cycles alone between operation temperature and room temperature [63]. It seems plausible due to sulfur contamination on nickel since the nickel–sulfur system exhibits significant lowering of liquidus temperature due to the eutectic formation; thus eutectics appear even below 800°C.

In any case, change in microstructure is a complicated matter, and detailed analyses should be made not only on nickel but also on oxide component or pore [85]. In recent years, the investigation on microstructure with FIB-SEM or XCT has been rapidly progressed [86–88]. It is therefore expected that sintering behavior and related phenomena will be well clarified in its relation to degradation.

Carbon Deposition Since hydrocarbons are important fuels for SOFC, carbon deposition should be avoided [89]. When carbon deposition once starts, this destroys the microstructure of Ni-cermet anode and deposited carbon acts as catalyst for further deposition so that a large amount of carbon can block the flow of fuels. Since the decomposition temperature of hydrocarbons decreases with increasing carbon number in hydrocarbons, the possibility of carbon

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 12
Systematic investigation on the anode degradation as functions of current density and water content in fuels with a parameter of electrical potential (From [83, 84])

deposition increases with carbon number. On the other hand, water vapors are emitted from the electrochemically active sites and this promotes the steam reforming. Thus, under cell operation, the possibility of carbon deposition decreases in the vicinity of active sites.

Sulfur Poisoning Sulfur contaminations inside SOFC stacks depend on the system configuration. For the small stationary applications, desulfurization process is first placed before the reforming process; this is because the reforming catalysis is week against sulfur contamination. In such a case, essentially no sulfur poisoning can be expected during the normal procedure of SOFC operation.

For diesel fuels, on the other hand, the presence of sulfur, and possible sulfur poisoning, is strongly related with the degree of reforming [90].

In recent years, it has been found that sulfur contamination appears even when sulfur-free fuel such as hydrogen is utilized [66]. This strongly suggests that sulfur sources are not only from fuels but also from other components. Most probable source is metal components in stacks and thermal insulating substances containing metal sulfates.

Performance degradation of nickel anode due to sulfur consists typically of two stages [90–100]. The first stage is the prompt response against the introduction of hydrogen sulfur, namely, stepwise decrease of electrical potential. The potential drop is well correlated with the sulfur coverage on Ni [96]. This is usually recovered when sulfur-containing fuels switch back to noncontaminated fuels; this is quite a slow process. The second stage is a process following the first stepwise change; when concentration is low, there is no further change, whereas some irreversible lowering in electrical potential is observed when concentration is high.

Furthermore, effects of sulfur can appear in a more significant and fatal manner. In an experiment by Julich research center, the cell performance was tested in hydrogen fuel containing 50 ppm H_2S. After the initial decrease in potential, the performance was maintained at this low level. However, after about 150 h, the cell suddenly died. Posttest examination clarified that NiS spread out in the interface region between YSZ electrolyte and nickel cermets. In addition, $NiSO_4$ was formed inside the anode layer. These features contradicted with the expected Ni-S interaction predicted from the thermodynamic equilibrium [85]. There must be some mechanism to enhance the effect of sulfur and to accumulate sulfur at the TPB vicinity. One possible explanation is the irreversible nature of the electrochemical side reactions under the anodically polarized current, that is, the sulfur deposition is described as the following anodic reaction:

$$H_2S(g) + 0.5\ O^{2-} = S(\text{on Ni}) + H_2O(g) + e^- \quad (1)$$

On the other hand, the volatilization reaction can be written as follows:

$$S(\text{on Ni}) + 2O^{2-} = SO_2(g) + 4e^- \quad (2)$$

When two reactions take place continuously, adsorption sulfur can be maintained at a certain coverage on Ni. For a long period of operation time, sulfur can be accumulated inside nickel particle as a result of dissolution and diffusion of sulfur.

Other Impurities Figure 8 shows the actually observed impurities. Among them, effects of silicon have been extensively investigated [101–106].

Recently, investigation on the impurities derived from coal-base gases has been made extensively in the SECA project of US Department of Energy (DOE), which promotes the utilization of coals in SOFC [107]. They first made thermodynamic analyses on chemical behavior of impurities in gasification process and hot gas cleaning process, and then categorized impurity elements into several classes [108, 109]; furthermore, they made a series of experiments to examine those elements which are regarded as possible poisoning elements to nickel anodes [110–114]; the following is a brief summary of their results in comparison with other related investigations [115–123].

1. Phosphor and Arsine show the strong affinity with nickel to form intermetallic compounds. In button cell experiments, intermetallic compounds are formed outside of the anode layer, which indicates that the reaction rate is fast and the diffusion of Ni to reaction sites is fast too. For AsH_3 gas, cell performance does not show any changes for a while despite the formation of intermetallic compound and suddenly dies. This is probably because the electrical path was broken due to the nickel deformation. For PH_3, on the contrary, the cell performance

degrades from the starting time. This is probably due to the formation of $HPO_2(g)$ [116–123] which attacks the electrochemical sites.

2. Sulfur and Selenium exhibit similar behavior when the concentration of H_2S or H_2Se is low. Namely, the abrupt initial change occurs first and then constant performance is maintained. Difference can be seen in the recovery behavior from the contaminated fuel to noncontaminated fuel. For H_2S, a slow recovery process appears, whereas no recovery process appears for H_2Se. Furthermore, severe damage may be caused for H_2Se. The common feature is that damage parts are always in the interface region between electrolyte and anodes.

Generalized Model for Degradation due to Gaseous Impurities

Yokokawa et al. [8] made thermodynamic analyses on the interaction between cathodes/anodes and gaseous impurities. By comparison between the thermodynamic reactivity and the electrode degradation behaviors, they have extracted generalized models for degradation. It can be summarized as in Fig. 13, where the characteristic features concerning degradations are plotted by using variables for the transported amount of impurities and for the thermodynamic affinity between electrode and gaseous impurities, for example, for perovskite cathodes, the thermodynamic activity of SrO can be adopted, whereas for anodes, the interaction parameters of systems for forming nickel intermetallic alloys can be used. Essential points in the generalized models are:

1. When the electrochemical activity is lowered due to the impurities, the electrochemical reaction sites should be covered by such impurities. In this case, it is no need that the covered atoms have the strong chemical interactions with electrode materials. The deposition or adsorption is enough to disturb the fundamental steps in the electrode reaction mechanisms. On the other hand, when cell performance is changed due to changes in electrical path or gaseous channel, the accumulated amount of deposited or reacted impurities should be large. This difference should be quite significant. For example, in the Cr poisoning, only a thin layer of deposited chromium in the order of several nanometers on reaction sites is enough to lower the cell performance in the order of 10%. On the other hand, since the electrical path or gas channel are made of the particles or pores in the order of several micrometers in size. This implies that a large amount of $SrCrO_4$ is needed to block the electrical current or the gaseous flow.
2. There can be two different reactions for impurity behaviors, namely, electrochemical side reaction and normal chemical reaction. The most important feature of the degradation is that the degradation reaction takes place under the flow of the electrochemically active species. This suggests that in the cathodic polarization, the electrochemical reduction (cathodic reaction) is accelerated. For example, chromium-containing vapors, $CrO_3(g)$ or $CrO_2(OH)_2(g)$, can be easily reduced to form Cr_2O_3 at the electrochemically active sites and as a result, the electrochemical activity of active sites decreases due to the coverage of no electrical conductive and no catalytically active substances.
3. On the other hand, recovery processes also have two contributions from the chemical and the electrochemical reactions; the latter is given in equation [2], which was derived from considerations on the difference in the recovery process between S and Se.
4. When the chemical interaction between the electrode components and the gaseous impurities is strong, there arise many processes inside the electrode area and respective processes have their own activated process. As a result, their appearance as degradation behavior is quite different from experiment to experiment. Typical example is the effect of Cr vapors on the electrode activity of LSF- or LSC-based active cathodes.

After establishing the general model for degradation due to impurities, it becomes possible to consider all possible effects on a particular case of specified electrode and impurity.

Cost Issues

Cost Issues in Relation to Durability/Reliability and Performance

Cost, performance, and durability are important figures of fuel cell systems and for SOFCs, these three

Solid Oxide Fuel Cell Materials: Durability, Reliability and Cost. Figure 13
Generalized model for electrode-impurity interactions and their relation to degradation: (**a**) chemical phenomena as functions of transported amount of impurities and chemical affinity between electrode materials and (**b**) three fundamental regions for electrode-impurity interaction

aspects are closely related with each other. This can be summarized as follows:

1. Costs consist of materials cost, cell/stack fabrication cost, and system cost. Whenever durability has been improved by changing materials or materials processing, usually it costs more due to additional treatments, etc. Thus, there is a trade-off relation between durability and cost. To overcome this relation, innovative breakthrough is needed to stage up this relation.
2. When cell performance will be improved, this benefit can be used in increasing the conversion efficiency or in increasing operating current density to reduce the mass to realize rated power, leading to cost reduction per rated power.

As described in the introduction, SOFC stack development started with the breakthrough by Westinghouse; the sealless tubular cells can be categorized as stable but expensive stacks. Since then, many efforts

have been focused on reducing the fabrication cost in the first-generation cells.

On the other hand, there has been a big wave to construct the second-generation cells to be operated at lower temperatures around 800°C. When the first-generation cells are operated at low temperatures, the Ohmic loss in electrolyte and the overpotential in cathode become quite big. Therefore, in the second-generation cells, use is made of thinner electrolytes and more active cathode materials. Interestingly enough, the performance (conversion efficiency) of second-generation cells becomes much better than that of the first generation. This is mainly because the active cathodes such as LSCF exhibit excellent performance even at low temperatures and also handling of the thinner electrolyte provides some improvement even for fabricating the cathode layer; as a result, performance becomes better. Even so, the active cathodes such as LSCF are chemically reactive, for example, LSCF reacts with CO_2(g), CrO_3(g) and SO_2(g) to form $SrCO_3$, $SrCrO_4$ or $SrSO_4$. This is directly related with the long-term durability.

Cost in Relation to Applications

Since the first-generation cells were aimed at larger stationary applications, several cost evaluations were made on such applications [31, 124–130]. These considerations are focused on the followings points:

1. Identification of high cost element. The most expensive elements are Y in YSZ, La in cathodes or oxide interconnects; Co in LSCF, Ni in anode can be also categorized as rather expensive materials. To avoid the utilization of such elements, it is required to adopt redesigned stack structure with appropriate fabrication methods.
2. Cheaper materials if acceptable; particularly, impurities will be an issue.
3. Reduction of the number of the components in repetitive units of stacks.
4. Reduction of losses during fabrication.
5. Automation of production.

There are generalized arguments on the relation between cost and performance:

1. Roles of raw materials: as the structural component, the low price materials are thought to be used, whereas for the highly functional materials, there are some arguments: A typical example is the utilization of scandium [131]. Although the raw materials cost for scandium oxides is much higher than that for yttrium oxide, there are many groups who are interested in utilizing ScSZ instead of YSZ. This is based on an idea that despite higher raw materials cost, the higher performance leads to reduction of total cost of stacks to be required to achieve a given rated power.
2. Even when low-cost materials are used, additional procedures are needed to achieve the required reliability and durability. Therefore, cost should be considered in combination of raw materials cost and fabrication cost. This is particularly true for metal interconnects; metal interconnects are cheap in materials cost compared with La-based oxide but additional procedure of coating increases the fabrication cost.

In 1998, BMW, Delphi, and Renault announced the application of SOFC as APU (Auxiliary Power Units) of automotive. This gave rise to drastic changes in applications of SOFC systems. The US Department of Energy started a new project called SECA (Solid State Energy Converter Alliance). Their cost target is about \$150/kW for stacks and \$700/kW for system in the mass production level. Recently, an interesting analysis [132] has been made on the operation modes of the degraded stacks in its relation to total system cost. There can be two operation modes; one is to keep the same current density, the other being to keep the same electrical potential. This difference gives rise to a large difference in strategies in the replacement of the stack itself and overdesign.

1. Under constant current operation, some degradation leads to lowering the electrical potential and as a result, power output is correspondingly lowered. Since the conversion efficiency is also lowered, heats produced inside stacks increases. To remove excess heats, a larger amount of air has to be flowed. For this purpose, additional energy is required and total efficiency is further decreased. In this sense, operation is continued under a rather severer condition. Further degradation can take place under such a condition. In addition, one needs to keep a large capacity of BOP to ensure the capacity for air flow

in an excess amount. In view of these features, this operation mode must only be appropriate for stacks with extremely low degradation rate.

2. Under constant voltage operation, current density decreases largely in contrast and as a result, power output is also correspondingly lowered significantly. However, efficiency is maintained rather constant and therefore there is no need to keep a large capacity of BOP. Since power output per one unit decreases significantly, additional stack capacity is required to offset for such a loss of capacity. In this operation mode, damage on stacks is not severe so that stacks can be operated for a longer period of time, and this is an important advantage against the constant current operation mode.

Future Directions

There are a number of degradation issues which are still unclear and need to be addressed in the future:

Stack Behavior

Stack behaviors are characterized in terms of temperature distribution, current density distribution, flow distribution, etc. Among them, current distribution is very important in determining stack performance, stack temperature distribution, etc., but is hard to be measured in real stacks. In many cases, the information on current distribution is obtained from the simulation technique. In this sense, simulation technique becomes quite important. It is still highly hoped that progress in experimental technique will be made in obtaining the current density distribution in stacks.

From the materials point of view, many stacks consist of ceramics and metals. Ceramics may exhibit oxygen nonstoichiometry and change their volume in a complicated manner as functions of temperature and pressure. On the other hand, metals and alloys can be deformed under stresses/loads. When those two materials are utilized under a long-term operation at constant temperature or under frequent thermal cycles, mechanical interactions between two materials become important.

Effects of High Conductive Electrolyte

There can be seen one interesting feature in the low-temperature SOFC, that is, the cell performance of the anode support cells has been much improved compared with electrolyte self support cells. This is apparently due to the lowering of the ohmic resistance inside electrolyte. Furthermore, the electrode performance is also improved very much. This can be ascribed to better fabrication procedure. When thin electrolyte is fabricated, very fine structure is designed and fabricated. In a similar manner, cathodes are fabricated carefully so that it is expected that microstructure of cathodes is well established. These features can be summarized as follows: When the conductance is improved and the homogeneous current flow is established inside electrolyte, electrode performance can be maximized by fabricating the electrode layer without faults. This is a matter of the current density distribution inside one cell. This is determined in terms of the homogeneous ionic current, homogeneously distributed electrochemical sites, and homogeneous electronic current. If there is some fault among them, this leads to inhomogeneous current flow and therefore some degradation may take place.

Here, an interesting finding by Watanabe and Uchida [133] should be referred to: that the electrode performance becomes higher with those electrolytes having the higher ionic conductivity. The proper mechanism of this finding has not been given fully but the current density distribution in the vicinity of electrochemically active sites may be different between those electrolytes having different ionic conductivities.

Advances in Characterization

The electrode performance is determined by many factors. Among them, the microstructure is one of the very important factors. Even so, it has not been easy to make characterization on the microstructure in an appropriate way. For example, in nickel cermet electrode, the connection of nickel is important in addition to the skeleton structure of oxide network. Since nickel is dissolved into acid, it is easy to extract the skeleton structure of zirconia. On the other hand, nickel network is not well determined experimentally. Recent advances in the experimental determination of three-dimensional electrode structures by FIB-SEM or by XCT techniques make it possible to evaluate details of microstructure changes in nickel cermets. For example, the most important physicochemical measure of the

electrode is the length of three phase (electrolyte oxide, electronic conductive metal, and gases) boundaries. Recent experimental and related theoretical progress makes it possible to reconstruct the cermet electrode in computer space and to identify the ionic path, electron path, and electrochemically active sites in combination with appropriate electrode reaction mechanisms. This provides a powerful tool for investigating the mechanism of degradation in terms of fuel cell operation variables such as time, current density, etc. Thus, it is highly recommended to investigate in more details the microstructure and its relation to electrode activity.

Intermediate Temperature Gaseous Species

Most typical degradation is chromium poisoning. This is caused by the gaseous species such as $CrO_3(g)$ or $Cr_2O_2(OH)(g)$. In order to understand the chromium poisoning, thermodynamic analyses on those gaseous species are essential. Fortunately, those data are available so that detailed analyses were made successfully. For the Ni-P system, the vapors, $HPO_x(X = 1,2,3)$ play an important role according to Bao et al. [116–118]. Without considerations on such gaseous species, no proper transportation mechanism can be obtained. An important point of these analyses is that the partial pressure of such species is extremely small in the range of 10^{-12} to 10^{-6} atm.

Although the accurate determination of the partial pressure of electrochemically important species is highly required, there can be some difficulties:

(a) Lack of the thermodynamic properties of those gaseous species which can be dominant in the intermediate temperature region. This is particularly true for species which are emitted in the presence of water vapors.
(b) Some uncertainty in the already available thermodynamic data.

Thus, the intermediate temperature gas chemistry should progress for the electrochemical purpose.

Effects of Minor Species

Minor carriers in electrolyte can also make contributions to degradation, although apparent effects have not been fully clarified. Most important minor carrier in the fluorite-type oxides is proton. It is well know that the proton concentration in YSZ is in the order of 10^{-5} in mole base. Correspondingly, the transportation number can be evaluated to be in the same order. Normally, it is quite difficult to detect this effect in the electrical performance so that in many electrode reaction models, any role of protons is neglected particularly in cathodes. In the fuel cell operation mode, protons are formed in anode and migrated to cathodes, leading to the emission of water vapors on the cathode side. In view of this nature, it is expected that the formation of hydroxide compounds can be expected as an electrochemical side reaction. $Sr(OH)_2(g)$ must be interesting in view of the proposed mechanism of Sr migration in the form of gaseous species. In addition, the $Cr_2O_2(OH)_2(g)$ emission can also be expected from the reaction of deposited Cr_2O_3 with transported protons and oxygen atom. This reaction should be considered as the recovering (heeling) process of Cr poisoning. Note also that because proton concentrations in doped ceria is two orders of magnitude higher than that in YSZ, the utilization of doped ceria as reaction/diffusion barrier can also provide enhancing effects of such recovering (heeling) process. It is hoped to clarify such effects in relation to a long-term stability of cathode materials.

Anode The negative terminal of the SOFC where oxygen ions from the electrolyte react with fuel releasing electrons to the external circuit.

Cathode The positive terminal of the SOFC where oxygen molecules from the air are reduced to oxygen ions by absorbing electrons from the external circuit.

Electrolyte The central component of the SOFC which conducts electricity by the movement of oxygen ions. This is the solid analogue of the liquid electrolyte used in a battery.

Fuel cell stack A fuel cell composed of several individual fuel cell (anode/electrolyte/cathode) units electrically interconnected in order to provide a useful device in terms of power output.

Heterostructure A structure consisting of two closely matched materials with properties superior to those of the individual components due primarily to interface effects. Can be further enhanced through creation of multilayer heterostructures where many repeats are generated.

Planar device A fuel cell constructed from sequential functional layers of anode, electrolyte, and cathode in a planar geometry.

Solid oxide fuel cell (SOFC) An electrochemical device for the conversion of a gaseous fuel into electrical energy using oxide ion-conducting ceramic membranes.

Definition of the Subject and Its Importance

The Solid Oxide Fuel Cell is an electrochemical device for the conversion of hydrogen or a hydrocarbon fuel directly into electrical power. They are clean, modular, and efficient and retain this efficiency across a wide range of sizes. This fuel flexibility and efficiency makes them very attractive for a number of power-generation roles, including distributed generation and combined heat and power applications, where they could make a significant impact on carbon-emission reductions and provide a pathway towards an eventual low carbon economy. There are some significant hurdles to be overcome before there is a global uptake of SOFC technology, and it is very likely that the technology will evolve markedly over the next few decades. It is thus important to take a forward look at how the technology may evolve and what kinds of devices, materials, and diagnostics will be needed to assure this continued development.

Introduction

Although Solid Oxide Fuel Cells (SOFCs) have been investigated since their discovery by Sir William Grove in the nineteenth century, little progress was made until almost a century later when the twin drivers of security of supply and the reduction of carbon emissions provided the necessary financial and political imperatives to accelerate SOFC development. Since that time, there have been a number of generations of devices, from the early tubular cells developed by Westinghouse and Mitsubishi Heavy Industries, through planar electrolyte supported cells, to the current generation of supported thin-film planar devices, which are nearing commercial exploitation, operating at intermediate temperatures (ITSOFCs). Much has been written on the materials and device characteristics in journal articles, conference proceedings, and there are many reference books [1, 2]. The aim of this article is not to replicate these many excellent texts, but to present quite a different view, one which looks towards the future of SOFC technology and what new designs, new materials, and new diagnostic techniques will be required to meet the demands of future SOFC developments.

From the current perspective, the future of SOFC technology looks promising. SOFCs will have many roles to play in the global energy scenario, from large-scale central power generation, distributed generation roles in domestic and district Combined Heat and Power (CHP), to mobile, remote, and standby power. If this outlook is correct, then the SOFC will undergo continued development to achieve improved performance and durability and will become more commercially viable in the very near future, delivering substantial increases in the efficient use of hydrocarbon fuels and a consequent drop in carbon emissions. In considering the future, it is thus important to look at how the technology will develop into new SOFC concepts. These have lagged behind mainstream SOFC development, but could quickly benefit from any significant technological advances made in their development. One thing is clear; these developments are underpinned by the requirements for new materials and new diagnostic techniques. The materials must meet stringent requirements for electrical and mechanical properties coupled with long-term stability in the appropriate environment. The purpose of this contribution is to describe these possible novel SOFC and SOFC-related concepts, describe their strengths and their drawbacks, and in parallel to explore the advances

in materials and materials characterization that will be necessary to ensure application and commercialization in the future.

Novel Devices and Configurations

SOFCs have largely converged on standard configurations, such as tubular or planar, with the structural support provided by the electrolyte, the anode, the metallic interconnector, or an inert porous support material. Each of these concepts has its own combination of advantages and disadvantages. In this section, some "unconventional" SOFC configurations and devices are discussed, and their performance and potential applications are considered in comparison with the more conventional approaches. This will include microtubular fuel cells, mixed reactant fuel cells, micro-planar fuel cells, and dual proton-oxygen ion fuel cells.

Microtubular SOFCs

Tubular SOFCs are not new and have been developed for large-scale stationary CHP applications with both circular and flat-cross sections. A major advantage of tubular SOFCs is better tolerance of thermal cycling, especially if one end is closed and therefore unconstrained to allow thermal expansion-length changes. A major disadvantage is that the volumetric power density is smaller than for a planar configuration, although this is partially offset with a flat cross-section tube. However, another way of improving the volumetric power density is to make the tubes smaller in diameter. When the diameter is less than approximately 3 mm, these are referred to as microtubular cells and their development has recently been reviewed by Lawlor et al. [3] and Kendall [4]. The reduction in diameter brings additional advantages in that the small tubes tend to have higher mean strength because the stressed volumes are smaller and lower variability in strength as the processing tends to give a more uniform microstructure. Consequently, microtubular SOFCs tend to have excellent thermal cycling durability.

The most usual configuration is a thin film of electrolyte on an anode support tube and an outer thick-film cathode. However, a major problem with the microtubular concept is with current collection from the electrodes and interconnection into stacks. Since the tubes are so small, large numbers are required for applications requiring appreciable power. For example, a typical tube with diameter 2 mm and length 100 mm operating at 0.2 W cm^{-2} only produces 1.25 W. Sammes et al. [5] have described a serpentine interconnection system for anode-supported tubes of conventional SOFC materials that are somewhat larger than the usual microtubular size, being 13 mm diameter and 110 mm long. However, at 850°C, the maximum power density was only 0.1 W cm^{-2} and was limited by the current collection along the cathode.

Suzuki et al. [6, 7] have attempted to overcome this problem with a cubic stack design (Fig. 1) in which microtubular SOFCs are assembled in layers joined by a porous matrix of cathode material. The layers are assembled in stacks in which individual layers are electrically insulated from each other by a glass and the cathodes of one layer are connected to the anodes of the next using silver. Each microtube was 0.8 mm in diameter and 8 mm in length and made from a Ni/$Ce_{1-x}Gd_xO_{2-\delta}$ (CGO) composite anode material. The electrolyte was CGO and the cathode an $La_{1-x}Sr_xCo_{1-y}Fe_yO_{3-\delta}$ (LSCF)/CGO composite. The stack consisted of 20 cells; 4 layers of 5 cells; and its performance is also shown in Fig. 1. At 500°C, the power output of a single tube was 0.32 W cm^{-2} at 0.7 V, and the total-bundle power at 490°C and 0.7 V per cell was approximately 1.3 W; corresponding to 0.25 W cm^{-2}. These are impressive performance figures at such low operating temperatures. However, the fabrication of these stacks could be difficult to automate and the final structure is monolithic, so that much of the tolerance of the tubular configuration to thermal gradient stresses is compromised.

Mixed Reactant Fuel Cells

A major problem with almost all SOFC designs is the requirement to seal the structure in order to prevent the fuel and oxidant gases from coming into direct contact and causing direct combustion of the fuel. One possible way around this is to operate the cell at a temperature below which no direct combustion will take place and to allow the fuel and oxidant to mix. The cell then requires very selective electro-catalytic electrodes in order to generate electrochemical power. Ideally, the anode should only catalyze the

Solid Oxide Fuel Cells. Figure 1
(**a**) Micro-tubular SOFC stack layer concept and (**b**) performance of a 20 cell (4 layers) bundle [6, 7]. Reproduced with permission

fuel-electrochemical oxidation and the cathode the electrochemical reduction of the oxidant. Neither electrode should catalyze direct chemical reaction of fuel and oxidant.

The first attempts at such a configuration were reported by Hibino and Iwahara, [8] and there have been many subsequently. The area has recently been reviewed by Yano et al. [9], and some typical configurations are illustrated in Fig. 2. There are many reports of good power densities when operating on hydrocarbon fuels, which are more resistant to direct oxidation

Solid Oxide Fuel Cells. Figure 2
Geometries for planar mixed reactant SOFCs [7]

than hydrogen. However, there is always some direct combustion and the cell temperature can be considerably higher than the nominal ambient temperature as a result, which makes the performance difficult to judge. Some direct combustion might even be regarded as an advantage since it can help small SOFCs to be thermally self-sustaining. Riess [10] has discussed the issues involved in mixed-reactant mode and pointed out that to date they can only operate with low fuel utilization and short gas residence times (high-flow rates). He proposes a configuration similar to that being investigated in mixed reactant PEMFCs that is illustrated in Fig. 3. All the components are porous, so that the mixed-reactant gas stream flows through the whole unit. This concept enables high fuel utilization to be achieved in principle, but has not yet been realized in practice since the selectivity of the electrode catalysis is not good enough for the materials investigated thus far.

Micro-planar SOFCs

These devices feature the use of micro-fabrication techniques adapted from the micro-electronics industry. These encompass substrate etching, thin-film deposition, lithography, and film-etching steps. This field has recently been reviewed by Evans et al. [11], and all devices exhibit the beautiful structural quality resulting from the micro-fabrication techniques. An example of a micro-planar SOFC fabricated on a silicon substrate is illustrated in Fig. 4 [12]. Figure 4a shows the sequence of fabrication steps used to make the edge-supported SOFC membrane which spans an aperture

with dimensions 600 × 600 μm. The yttria stabilized zirconia (YSZ) electrolyte, which is only 70-nm thick, was deposited by atomic-layer deposition and is corrugated in order to increase the active area and accommodate thermal and fabrication strains. An image of the corrugated electrolyte is shown in Fig. 4b. The electrodes are 120-nm thick porous-Pt deposited by sputtering. The performance, of both flat and corrugated cells, on hydrogen is remarkable (Fig. 4c), with a maximum power density of 0.86 W cm^{-2} at 450°C. The shape of the *V–I* characteristic indicates large overpotentials at the electrodes and therefore the possibility of large power density at more useful terminal voltage with improved electrodes.

At this stage of development, the reported results indicate that good performance is likely to be achievable with micro-fabricated SOFCs. However, more problematic are the engineering issues related to thermal management and fuel utilization that are more difficult to deal with as the device becomes smaller. Even if these problems are solved, the power levels and total energies are so small that the impact on sustainable electrical energy generation will be small and the development of these devices will be driven by convenience of operation (e.g., in consumer electronics) rather than energy efficiency.

Dual Proton-Oxygen Ion-Conducting Cells

Recently, a new concept (Fig. 5) has been proposed, called the IDEAL-Cell which attempts to combine the advantages of both proton-conducting and oxygen ion-conducting SOFCs [13]. The anode electrode reaction is as in a proton-conducting SOFC, and the cathode reaction as in an oxygen ion-conducting SOFC. In the central chamber, which contains a porous mixture of the two electrolytes, the protons and oxygen ions combine to give the product water. In this way, the water reaction product does not interfere with either of the electrode reactions. A "proof-of-concept" small cell was fabricated with yttrium-doped barium cerate as the proton-conducting electrolyte and yttrium-doped ceria as the oxygen ion-conducting electrolyte. The test cell achieved an encouraging maximum power output approaching 0.5 W cm^{-2} at 600°C on oxygen and humidified hydrogen. It will be interesting to see whether this concept can actually deliver the anticipated benefits on a larger scale.

Novel Materials

In the preceding section, new design concepts for the SOFC for application in the near future were discussed. One common feature of most of these new concepts is the lowering of the operating temperature into a new regime (400–600°C), where high performance materials should make a significant impact. The active components of such solid oxide fuel cells must conform to some very stringent materials requirements. The prime need is to have very high diffusion coefficients for the oxide ion at these low temperatures which will require considerable materials development for both electrolytes and the mixed conductors used as electrodes. In this lower temperature regime, the three active components: anode, cathode, and electrolyte, each contribute towards the overall area specific resistance (ASR) of the cell. Of these three components, the two that have received the most attention are the electrolyte and the cathode, which is known to give rise to the largest ASR below temperatures of 650°C [2].

Before moving to the details of these materials, it is instructive to examine the atomistic quantities that govern the transport of oxygen in these oxides. A simple Arrhenius-type expression describes the diffusion coefficient of oxygen, D, in oxide materials.

Solid Oxide Fuel Cells. Figure 4

Solid Oxide Fuel Cells. Figure 5

The concept of a dual proton and oxygen ion SOFC [13]. Reproduced with permission

$$D = D_0 \exp\left\{\frac{-E_a}{RT}\right\}$$

where D_0 is the pre-exponential factor which contains terms relating to the concentration of oxygen defects and E_a is the activation energy for diffusion which can contain terms relating to the formation, association, and migration of the defects on the oxygen sublattice [14]. Both terms are important in achieving high diffusivities. Materials with highly defective oxygen sublattices or high concentrations of interstitials are commonly investigated to give high diffusion coefficients; however, a low activation energy is essential to retaining the high-diffusion coefficient to low temperatures. This means minimizing (or removing) any

terms due to the formation or association of defects and ensuring that the mobile oxygen ions can migrate with the minimum of hindrance. These criteria apply to materials that have very high ionic transport numbers for use as electrolyte materials as well as to mixed conducting materials used as electrodes.

An additional criterion for mixed conducting materials used as cathodes is that they should have a high surface exchange rate (k) for oxygen. This quantity also follows Arrhenius-type behavior, although the atomistic parameters that govern the exchange process are still somewhat obscure. However, it is well known that materials that have high oxygen-diffusion coefficients usually have high oxygen-exchange coefficients because both are related to the oxygen mobility in the material [15]. It should be remembered that the selection criteria described above are only part of the process of the selection and optimization of new materials for the application in solid oxide fuel cells, and that a significant part of the application of new materials relies upon the development of appropriate ceramic processing to yield a suitable microstructure for the SOFC cathode [16].

In the following paragraphs some of the current materials research that could give rise to suitable materials for applications in SOFCs is described.

Electrolyte Materials

The materials requirements described above for obtaining high oxygen transport can be further developed [17] and have been used for many years in the optimization of new oxygen ion conductors. A good example of this are the materials formed from ceria gadolinia solid solutions that have some of the highest conductivities at low temperatures. Fig. 6 shows an Arrhenius plot of the conductivity of most of the conventional oxide ion conductors used as electrolytes. New ionic conductors are emerging as further compositions are explored, such as the $La_2Mo_2O_9$ (LAMOX) family and the apatite-structure materials, however they usually offer incremental advantages and do not have either the low-temperature conductivity offered by the cerias or the very high stability offered by the stabilized zirconia materials. At 600°C, some very high ionic conductivities can be achieved by bismuth-based

Solid Oxide Fuel Cells. Figure 6
Comparison of the lattice conductivity of some well known oxide ion conductors. Data taken from [18–26]

materials, on the order of 10^{-1} S cm^{-1} which is equivalent to that of yttria-stabilized zirconia at 1,000°C; however, these materials suffer from poor stability in reducing atmospheres and are thus not suitable to act as SOFC electrolytes without some form of protective layer. Other than the bismuth materials, there is a paucity of materials that can display conductivities of this order below temperatures of around 650–700°C.

Thin-Film Heterostructures

The continued search for materials that show better ionic transport, especially at low temperatures, has been a quest that has been pursued for many years. In the main, there have been two ways in which this search has been pursued: by the discovery of new materials, i.e., the optimization of the lattice mobility for the oxygen ion, as mentioned above, and more recently, by the investigation of nanomaterials and nanostructures, i.e., by the optimization of the interfacial transport of oxygen. Early work with thin (down to ~15nm) epitaxial yttria-stabilized zirconia (YSZ) films by Kosacki et al. [27] and Karthikeyan et al. [28] instigated a number of investigations into the effect of interfaces on conductivity. Kosacki et al.'s findings implied that the oxygen conductivity of the interfacial layer between the MgO substrate and the YSZ was strongly enhanced, by up to 3 or 4 orders of magnitude, and more significantly, that the activation energy was more than halved from 1.04 to 0.45 eV, important for achieving high values of conductivity at low temperatures. These findings prompted a number of subsequent investigations into the ionic conductivity of heterostructures, produced by pulsed laser deposition, involving thin layers of an oxide ion conductor (mostly YSZ) sandwiched between layers of insulating materials. The temperature dependence of the ionic conductivity for these materials is shown in Fig. 7, which shows that the conductivity can be either enhanced or suppressed over that for single crystal zirconia. By far the most significant result is that obtained by Garcia-Barriocanal et al. [18] (trace 10 in Figs. 6 and 7a in Fig. 7) who investigated very thin layers of YSZ and strontium titanate (STO) in samples made by sputtering. They observe that for epitaxial trilayers of 10 nm STO/1 nm YSZ/10 nm STO the conductivity was highly enhanced (trace 7a in Fig. 7), showing over 8 orders of magnitude of enhancement at 100°C. This is clearly much larger than any of the enhancements seen by other workers, most of which are grouped around 1–2 orders of enhancement of the conductivity of zirconia, depending upon the temperature. There is still much debate over these findings as, at the date of writing, they have not been repeated and there is controversy over the nature of the carrier, an electronic carrier would be much easier to reconcile with these high conductivities [31–33]. The interfacial strain at the STO/YSZ interface should be on the order of 7% which should not lead to a coherent interface as was observed by electron microscopy. Despite the lack of experimental evidence, there have been some theoretical studies including simulations by Density Functional Theory (DFT) which would tend to support the idea that the observed effects could indeed be ionic [34], although there is some doubt about the magnitude of the conductivity enhancement [35].

The most systematic of the subsequent investigations of heterostructures has been by Korte and coworkers [30, 36, 37], who have investigated a number of different interfaces by fabricating stabilized zirconia-insulator heterostructures using pulsed laser deposition. Recently, Korte et al. [38] have reviewed the current status of their (and other) work on multilayer structures and have classified them according to the degree of coherency of the crystal structure across the interfaces. They show that the lattice strain in the zirconia layers is important in determining the magnitude of the change in both conductivity and in activation energy. Tensile strain leads to an enhancement of the conductivity by up to an order of magnitude; however, the largest enhancement seen is in structures formed with calcia-stabilized zirconia (CSZ) and Al_2O_3 as the insulating layer, which have an incoherent interface and a disordered region and a high density of mismatch dislocations. The enhancement of conductivity seen is around a factor of 60 at 575°C with a lowering of the activation energy of almost 0.5 eV, a significant decrease, leading to increased low-temperature conductivity.

Korte et al. [38] speculate on the role of any misfit dislocations in the conductivity enhancement. This seems to be a likely explanation, as conductivity enhancement has been seen in YSZ single crystals that have been plastically deformed at high temperatures.

Solid Oxide Fuel Cells. Figure 7

Temperature dependence of the conductivity of oxide heterostructures. Data taken from Karthekeyan et al. [28], Kosacki et al. [27], Azad et al. [29], Korte et al. [30], Garcia-Barriocanal et al. [18]

Otsuka and coworkers [39, 40] have shown that the conductivity of material with high dislocation densities does show an enhancement of the conductivity and they estimate that the conductivity could be enhanced by a factor of 10^2–10^4. These findings clearly indicate a possible method for the enhancement of low-temperature conductivity in oxygen-ion conductors by the introduction of structures, such as heterointerfaces that give rise to either tensile strain or to large numbers of dislocations.

Electrode Materials

The search for new materials for electrodes has also been a long-term quest similar to the one mentioned above for electrolyte materials. Because of the importance of developing new cathode materials for low-temperature operation, much recent work has focussed on mixed electronic-ionic conducting materials for this particular application. Like the electrolyte materials, there have been indications that heterogeneous interfaces in mixed conductors can show some enhanced behavior [41], although there has been little published on this subject to date. Much of the conventional bulk materials have been based on highly substituted perovskite materials, such as $La_{1-x}Sr_xCoO_{3-\delta}$ for which substitution (x) can be as high as 0.6. There materials have very high strontium contents and high degrees of non-stoichiometry which give the materials high performance as cathodes, but bring a set of problems. The materials that have the highest levels of oxygen diffusivity, such as the cobalt-based materials mentioned above, also have high values of expansion coefficient (>20 ppm K^{-1}) [42], making them

thermo-mechanically incompatible with the electrolyte materials. In addition, the high strontium contents lead to vulnerability to long-term degradation problems [16] and possibly to chromium poisoning. In order to combat some of these problems, there has been a move towards materials that do not need high degrees of substitution and that could show greater stability while retaining the high electrochemical activity.

Of current interest is the work on layered crystal structures (which are almost a natural analogue of the heterostructures described above) in either polycrystalline or single crystal form. An example of a family of oxides with this layered structure is the Ln_2NiO_4 materials such as $La_2NiO_{4+\delta}$ or $Nd_2NiO_{4+\delta}$. These materials are the first member of the Ruddlesden Popper homologous series with the K_2NiF_4 structure, and they are unusual in that they show highly anisotropic conductivity (see for example Fig. 9 next section). The general structure of such $A_2BO_{4+\delta}$ oxides is shown in Fig. 8 and consist of alternating layers of perovskite ABO_3 and rocksalt AO layers. These materials are not substituted, but due to the variable valency of the B, cation tend to oxygen excess in air, i.e., $\delta > 0$, which can reach values of around 0.14. The oxygen interstitials are mobile in the AO layers and can give rise to substantial values of oxygen diffusivity. The expansion coefficients of these materials do not suffer from the very high values seen for the substituted perovskites, and so these materials are good candidates for next generation cathodes; however, their durability in cathode environments needs to be verified. Their performance, as ITSOFC cathode, has recently been reviewed and their suitability as candidates has been confirmed [43].

Solid Oxide Fuel Cells. Figure 8
Schematic of the crystal structure of $A_2BO_{4+\delta}$

Accelerated Materials Discovery

Accelerated materials discovery is of great interest for the development of the SOFC and a key goal for further development is the lowering of the operational temperature to below 600°C, the so-called intermediate-temperature regime. In this regime, cheap and readily available materials can be used for the balance of plant. When considering the need for novel materials, it is pertinent to consider the timescales needed for the introduction of new materials into devices to meet emissions reductions targets for 2030 and 2050 and beyond. Historically, the timescales for adoption of new materials/new technologies has been rather long, especially where the drivers (at least initially) are not financial. In order to have significant impact on the reduction of carbon emissions, wide-scale adoption of fuel cells has to take place over the timescale of the 20–30 years from 2010. Moving back down the development chain, this implies that any new materials must be adopted within the next decade or so, and the real scope of the task becomes apparent. How this can be achieved has been described in a short editorial by Kilner [44].

- Clearly, conventional trial and error methods of materials discovery are not going to meet this aggressive agenda and an accelerated form of materials discovery is needed. The important question is what type of accelerated materials development tools will become available? A new topic of "Materials Informatics" has emerged, which employs the use of large databases of materials properties obtained from conventional, combinatorial, or computational sources. The databases are then interrogated using techniques, such as data mining, neural networks, etc. This new and developing technique is still in its infancy, and very few databases exist which cover the functional properties of oxide ceramics.

  Much has been made of combinatorial approaches to materials discovery; however, there are many

barriers to the introduction of these methods to SOFC materials, not least their suitability to synthesize libraries of complex multicomponent oxides, such as the cathode materials $La_{1-x}Sr_xCo_{1-y}Fe_yO_{3-\delta}$ [45]. In addition to these limitations, there is the requirement for rapid screening methods to allow combinatorial libraries to be measured in an accelerated manner. This is not an easy problem to solve for applications that rely upon measuring complex electro-catalytic activity in very aggressive environments, such as SOFC electrodes.

Computer simulation offers an alternative way of providing guidelines for materials searching. For example, atomistic simulation of defects and transport in materials is well established; however, it is hardly a rapid process and much of the effort is expended in the rationalization of existing experimental data. A change in scope is needed to exploit the potential of such techniques to predictive materials screening.

It is important that these rather more pragmatic techniques, mentioned above, are developed in parallel with the more conventional intuitive methods to give development engineers rapid access to new materials.

Development of In Situ Diagnostics

Identifying and developing new materials for all components of a solid oxide fuel-cell system is only the first stage in producing a device. There are several key requirements, such as durability and compatibility, which have to be fully investigated before a material can be incorporated into a working fuel cell. As detailed earlier, this type of cell operates in a relatively harsh environment with a high temperature of operation and a wide pO_2 range. It is therefore essential to gain a full understanding of the behavior of each of the cell components and the stack itself as a function of all of these parameters in situ. Consequently, there has been an increasing demand for in situ characterization techniques to give real-time insights into device performance. Of course, in situ characterization covers a wide variety of techniques and properties. When discussing in situ characterization, it has to be considered that measurements are obtained as a function of either high temperature, variable pO_2, or electrical load, or indeed a combination of each of these. Many in situ studies focus on the structural characterization of individual materials, while further studies map the temperature distribution over a single fuel cell. In this section, the current status of in situ characterization of fuel cells and fuel cell materials are considered using a variety of techniques including diffraction and spectroscopy and some of the challenges are detailed that remain in fully understanding all of the processes; mechanical, structural, and electrochemical, that govern fuel-cell performance and durability.

In Situ Materials Characterization

In considering the development of new materials for fuel cells, many authors have used diffraction techniques to probe the high-temperature stability of individual components and to investigate any potential phase-transformation problems on thermal cycling. Information that can be obtained readily can be classified as either crystallographic (phase evolution/reactivity) or mechanical (stress evolution in ceramics). Initially, users are likely to consider the use of powder x-ray diffraction to investigate all of the individual functional components, given the relative ease of access to the equipment. However, the information obtained from x-ray techniques is limited by a number of factors, including the limited resolution of instruments and the dependence of the x-ray-scattering factors on atomic number, meaning access to information from elements, such as oxygen, is limited. There are many examples of information being derived successfully from x-ray diffraction studies with perhaps the simplest examples being the study of the reactivity of functional components at operating temperatures. Zhu et al. [46], for instance, have investigated the novel cathode material $PrBaCo_2O_{5+\delta}$ in contact with $Ce_{0.8}Sm_{0.2}O_{1.9}$ as a composite, finding no discernible reaction at temperatures up to 1,100°C, over only a short period of 3 h; while Sayers et al. [47] investigated nickelate cathodes on both Ce_{1-x} Gd_xO_{2-d} (CGO) and La_{1-x} Sr_x Ga_{1-y} Mg_yO_{3-d} (LSGM) electrolytes, finding differing degrees of reaction depending upon both time and temperature. Significant reactivity was identified by these authors with CGO at temperatures greater than 800°C. It was however noted that the in situ characterization of these reactions was limited by the data collection time and instrument resolution.

In determining the residual stress of an anode-supported SOFC, Fischer et al. [48] have used x-ray

diffraction to map the stress distribution as a function of processing and also have monitored the change in the stress state at room temperature and at 800°C. However, this study is limited by the operating temperature data having to be recorded after annealing, once the sample has returned to room temperature. Evidently, in situ characterization is of considerable value, but can be limited by the capabilities of the instrumentation/technique, and for SOFCs laboratory, x-ray techniques are certainly restricted.

For either higher resolution or greater phase discrimination, there are two main alternatives to laboratory x-ray techniques: synchrotron powder diffraction or neutron diffraction. Each of these techniques has its own advantages, with neutron-powder diffraction enabling access to light elements while synchrotron-diffraction experiments offer exceptionally high-peak resolution. The use of neutron diffraction at elevated temperature has proven to be invaluable in providing information on cathode materials in particular [49–54], while synchrotron sources have been at the forefront of the development of new techniques, such as 3 dimensional imaging of components.

Neutron Scattering Studies of Fuel Cell Oxides

Neutron diffraction has long been viewed as an essential tool for the structural characterization of novel materials [55, 56]. It is only relatively recently, however, that neutron diffraction has been used to characterize fuel cell oxides. Recent developments that have attracted researchers to the technique include the production of instruments that can offer small sample sizes and high-temperature stages with variable atmosphere capabilities, extending the in situ capabilities of this technique. Some of the earliest studies of fuel cell oxides were by necessity under ambient conditions and focussed on proton-conducting barium cerates [57–59] in which a structural distortion of $BaCe_{1-x}Nd_xO_{3-\delta}$ was determined and related to the release of spontaneous strain with increasing Nd content. Since these initial works, several authors have turned to neutron diffraction to gain additional structural information. Slater et al. [60] were among the first to use this technique to characterize an electrolyte material, $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{3-\delta}$. Here the authors identified a significant structural difference between the substituted material and the parent $LaGaO_3$, with the Sr- and Mg-substituted material adopting a more complex monoclinic structure at room temperature and undergoing several phase transitions on heating to 1,000°C. A tilting of GaO_6 octahedra was observed and related to the change in activation energy of conduction on heating identified from previous studies.

Use of neutron diffraction to study electrode materials in situ is a relatively recent development, with much of the current interest directed toward the phase evolution in novel cathodes with complex crystallography. Alonso [49] has provided an excellent review of the potential of neutron diffraction for characterizing fuel cell materials and detailed work on the La_2MO_{4+d} (M = Ni, Cu, Co) series of cathodes stating that the relationship between M–O distances and electrical properties can be readily determined as a function of temperature. With the $La_2MO_{4+\delta}$ materials, electrical changes occur on introduction of an A-site substituent, such as Sr, and the relationship between Sr content, apical M–O bond length, and total conductivity is resolved from this high resolution structural data. Further work by Skinner [54] focussed on the location of the oxygen interstitial, a particular strength of neutron scattering, identifying the relationship between oxygen content and phase, varying both temperature and atmosphere. Additionally, the two phase nature of the $La_2Ni_{1-x}Co_xO_{4+\delta}$ was clearly determined [61] from in situ studies where previous x-ray techniques had indicated a single phase. Information on the nature of the conduction properties of cathode materials can be inferred from the structural data obtained from these measurements, with Hou et al. [62] arguing that the nature of the Ni redox couple in $LaNi_{1-x}Mo_xO_3$ cathodes can be determined from the crystallographic data obtained. They also suggest that oxygen deficiency was observed leading to the potentially high oxide ion mobility required for a mixed conductor.

While this information on the crystal chemistry is of importance in determining the potential for new materials, it is the latest advances in data processing and interpretation that enable both structural and chemical information to be extracted from one data set. The advent of the Maximum Entropy Method (MEM) [63] for analysis of neutron-diffraction data has enabled authors to extract chemical-pathway data from the neutron density. Yashima et al. [64, 65] used

the MEM technique to visualize the diffusion pathway of the oxide ions in an anisotropic $Pr_2NiO_{4+\delta}$-based interstitial oxide ion conductor. The data obtained, Fig. 9, at temperatures of up to 812°C clearly illustrate 2-D diffusional pathways in the *ab* plane of the anisotropic crystal structure. This method has also been used to verify molecular dynamics studies of the isostructural $La_2NiO_{4+\delta}$ material [66], highlighting the benefits of combining both the experimental studies with simulation techniques.

Identification of novel conduction mechanisms is a particular strength of neutron techniques, and these studies have been extended to include the novel electrolyte apatite materials, with local defects identified [67–70]. Further electrolyte studies have included determining the total conductivity of the potential electrolyte, $La_2Mo_2O_9$, in situ through impedance spectroscopy and correlating these time-resolved data with structural transformations revealed through neutron-diffraction measurements [71, 72]. This relies upon the availability of well-designed experimental stages optimized for diffraction beamlines [71]. Engaging with central facilities to design, build, and commission this equipment is therefore essential.

JACS)

Synchrotron X-ray Studies

Synchrotron radiation is incredibly versatile allowing a wide variety of experimental techniques to be developed. Of direct interest to solid oxide fuel-cell science and technology are both diffraction and spectroscopy. Diffraction beamlines offer the potential to access complex structural information that is not revealed by competing diffraction techniques, while the spectroscopic techniques (X-ray Absorption Near Edge Spectroscopy [XANES]) and Extended X-ray Absorption Fine Structure [EXAFS]) allow users to access chemical information, such as redox kinetics. The latest developments include 3D tomography of complete cells which give unparalled information about the microstructure of composite electrodes [73, 74].

Synchrotron Diffraction In situ synchrotron x-ray-powder diffraction of fuel cell components has developed significantly over recent years as sample stages, and instrument development has enabled rapid data collection as a function of atmosphere with unprecedented resolution [75]. As the MEM technique can be applied to neutron diffraction data, so it can also be applied to synchrotron diffraction data, with Itoh et al. [76, 77] showing the complementary data obtained from combining both techniques. Through their investigation of $La_{1-x}Sr_xMnO_{3-\delta}$ (LSM)/$Ba_{1-x}Sr_xCo_{1-y}Fe_yO_3$ (BSCF) composites, they have determined both the ionic and electronic conduction pathways, with the synchrotron data highlighting isotropic Mn–O covalent bonds through which the electrons will pass, leading to good electronic conductivity.

As well as obtaining data as a function of temperature and atmosphere, Hagen et al. [78] have demonstrated that depth-resolved data acquisition from

NiO/YSZ cermets is possible. Using an advanced data collection mode employing a spiral slit and beamstop, the authors were able to follow the redox process between Ni and NiO. As the distance from the free anode surface increased, a reduction of the reaction rate was observed which is attributed to the difficulty of gas penetration to the electrode/electrolyte interface. As these data were obtained as a function of depth under redox conditions, a logical extension is to include larger operating cells in this environment to fully characterize structural/chemical changes under realistic conditions. These measurements could therefore have a dramatic impact upon cell development.

Residual stress within cells and components is evidently a key concern for developers of SOFCs [79], and analysis of this can readily be achieved using synchrotron x-ray studies. Villanova et al. [80] demonstrated the complementarity of both laboratory and synchrotron x-ray sources through their investigation of all components of the fuel cell. From lab x-ray studies they were able to determine residual stress in an anode-supported SOFC. Macroscopic stresses were determined in each layer through the analysis of lattice deformation. A significant finding of inhomogeneous stress distribution in the electrolyte led these authors to use the synchrotron technique to investigate the local stress from analysis of the stress tensor in the individual electrolyte grains.

A further study [81] examined the development of internal stress as a function of temperature for an anode-supported cell based on a Sc stabilized zirconia (ScSZ) electrolyte with a NiO-3 mol%-YSZ anode, finding that there were significant changes in the internal stress in both NiO and ScSZ that were not fully reversible, Fig. 10. Residual stress in the electrolyte was measured as a function of the reduction cycle and found to be 400 MPa in air, but decreased to 200 MPa on reduction of the NiO, and concluded that this redox cycle would be detrimental to SOFC performance.

While these studies are of importance, there are no studies of stress evolution in a complete functioning cell under electrical load, or indeed in a fuel cell stack, and this is evidently the next development step. The data obtained so far from synchrotron and laboratory x-ray studies highlight the potential of these techniques to advance the current understanding of failure mechanisms in operating SOFCs.

Solid Oxide Fuel Cells. Figure 10

Spectroscopy – XANES and EXAFS Spectroscopic techniques complement the diffraction measurements previously discussed as these target the local structure, giving details of the coordination environment surrounding particular chemical species. Thus, through control of the experimental conditions, it is feasible to extract chemical information from in situ measurements of fuel cell materials. There have been a number of initial studies of the room temperature and local structure of SOFC electrolytes, with Yamazaki et al. [82–84] considering the effect of dopants on the defect structure of $CeO_{2-\delta}$-based electrolytes. Further investigation of the Ce L_{III} edge spectra of ceria electrolytes was reported by Hormes et al. [85], who have also applied the same techniques to the cathode material $La_{1-x}Sr_xMnO_{3-\delta}$ (LSM). Each of these studies considered the bulk polycrystalline material, whereas Zhang et al. [86, 87] have used XANES to investigate the growth mechanism and crystallization of CeO_2 nanoparticles.

In considering LSM samples, significant differences in the local structure of thin film samples when compared with bulk LSM were observed [88], leading to the conclusion that the coordination environment of the Mn species is less distorted in the thin film. With the recent surge in interest in thin-film technologies for fuel cells, this may prove to be a significant finding and highlights the power of x-ray spectroscopy to

detect subtle differences that may have a dramatic impact on material performance.

The real strength of x-ray-absorption spectroscopy, however, is in extending these measurements to both time-resolved and temperature-dependent measurements. Species that are commonly found in solid oxide fuel-cell components are easily accessed as the techniques are element specific. As well as accessing element-specific information, the XANES technique is also sensitive to valence state, and hence redox processes and kinetic information can be extracted from in situ data. It is also straightforward to control the atmosphere under which the measurements are undertaken, so kinetics of both anode and cathode materials as functions of temperature, time, and pO_2 can be obtained. Indeed, this has recently been demonstrated with redox kinetics for fast oxide ion-conducting $CeNbO_{4+\delta}$ having been determined from Ce L_{III} edge XANES data [89].

3D Microtomography Perhaps one of the most exciting developments involving synchrotron radiation has been the advent of three-dimensional tomography [73, 74]. With this technique, it has been shown that detailed information about the internal structure of complex composites can be obtained, enabling researchers to gain vital information on the length of triple phase boundaries (TPB). This also allows the differentiation between active and inactive TPBs and has so far been demonstrated with anode cermets (Ni-YSZ). While not currently available as an in situ measurement, this is an obvious extension and is no doubt a future development for this technique. Currently these measurements are only available at a small number of sites worldwide, and hence this is a clear limitation. But as interest grows in this technique, it is highly likely that future developments at synchrotron sources will include this capability.

Wilson et al. [74] pioneered this technique using a Focussed Ion Beam slice and view method to allow the electrochemical performance and microstructure of materials to be quantitatively connected. In their pioneering work, a direct measurement of the TPB length was achieved through analysis of the reconstructed 3D anode, Fig. 11. From the analysis, they differentiate between interconnected and unconnected pathways, finding 63% of TPBs are interconnected. A high level

Solid Oxide Fuel Cells. Figure 11
3D reconstruction of the anode microstructure of a Ni-YSZ anode determined through the use of Focussed Ion Beam Imaging. (Reproduced with permission Wilson et al. Nat Mats)

of interconnection is required for electrochemical reactions to occur, and quantifying the microstructure in this way enables further optimization to proceed.

Shearing has adapted this process to incorporate a focussed ion beam lift-out technique, and in combination with software development, has shown that detailed phase contrast can be obtained from the Ni-YSZ couple, Fig. 12, leading to greater data quality and reduced uncertainty regarding redeposition of sputtered material. The use of this FIB tomography technique is unfortunately destructive [90], and hence the use of x-ray tomography presents an ideal opportunity to extract similar TPB information non-destructively [91]. While these data can be collected from standard x-ray systems, the use of a nano-CT system at a synchrotron source will enable higher resolutions to be achieved.

Raman Spectroscopy

Another promising in situ characterization method to have been proposed recently relies on the use of Raman spectroscopy [90, 92–94] to optically detect changes in the fuel cell under examination. Using Raman spectroscopy is entirely complementary to the previously discussed techniques and delivers data, for instance, on the heat distribution across a cell. Maher et al. [93] have

Solid Oxide Fuel Cells. Figure 12
Determination of anode microstructure and the extraction of active TPB length determined through FIB tomography. (Reproduced with permission Shearing et al. Figs. 4 and 5)

demonstrated the effective use of Raman spectroscopy with a Gd-substituted ceria in which the shift of a characteristic peak at 460 cm^{-1} can be correlated accurately with temperature and thus provides a method by which temperature distribution with high spatial resolution can be measured. Previously, the use of the Raman technique to determine the chemistry occurring at electrodes in SOFCs was highlighted [90], with particular emphasis on the monitoring of electrochemical processes at the anode. In this work, the disappearance of graphitic carbon was monitored as well as the kinetics of the Ni-NiO redox, and finally it was suggested that phonon modes of YSZ electrolytes could be correlated with lattice parameter changes, leading to a diagnostic for thermal gradients within cells. Subsequent work [95] has highlighted that oxidation processes can be monitored in situ and the effect of using carbon based fuels determined. Deposition of graphitic species (either ordered or disordered) was found to vary depending on carbon source and potential.

Summary

In situ characterization of solid oxide fuel cells can be achieved through the use of a variety of techniques to produce direct information on the chemistry, structure, and mechanical properties of the material/cell of interest. Rapid developments in test equipment offer ever greater levels of detail, with many techniques providing submicron resolution, and below, of the critical processes affecting solid oxide fuel-cell operation.

Particularly the non-destructive nature of many of these techniques allows full cycles of operation to potentially be analyzed and the causes of performance degradation to be determined.

Future Directions

Although the main aim of this article is to look at the future of the SOFC, this has been in the main a look at the near-term future and the possible designs and materials that the SOFC might move toward. The long-term future of the SOFC is much more difficult to predict because it will depend very heavily upon the diversity of renewable energy sources, what energy vectors are employed, and what fuels evolve to form the future energy mix. Most forecasters agree that the supply of usable hydrocarbons is limited and may already have peaked in the early part of the twenty-first century. The relative roles of newer fuels, such as bio-derived hydrocarbons and hydrogen in this future mix remains unclear; however, because of their high efficiency and fuel flexibility, it is likely that SOFCs will see widespread adoption and continued development in both the short- and long-term future.

Definition of the Subject

Clean and sufficient energy is an important precondition for the continued growth in global wealth. Solutions must be found to utilize the remaining fossil fuels more efficiently and also to ensure that new environmentally friendly fuels can secure power production in the post-fossil fuel era. This is the essence of the global energy challenge.

Fuel cells hold the promise of an efficient, low-pollution technology for production of electricity. Because fuel cells rely on electrochemical rather than thermo-mechanical processes in the conversion of fuel into electricity, the fuel cell is not limited by the Carnot efficiency as is the case for conventional generators. High-temperature fuel cells hold the promise of an efficient, low-pollution technology for production of electricity and efficient use of waste heat including low transmission losses. Scalability, decentralization, and load following capabilities are major advantages that can play an effective role in future power grids and power supply.

Solid oxide fuel cells offer the potential of high volumetric power density, cost-efficiency, and fuel flexibility, and significant progress has been made during the last 5 years in bringing SOFC technology closer to commercialization.

This entry will endeavor to answer the question whether SOFC technology is now ready for the market or perhaps put in another way: Is the market ready for SOFC technology and which challenges still need to be addressed?

Introduction

The entry will describe how SOFC technology can contribute to solving the energy challenges in the future. The current status of the SOFC technology and industry will be briefly discussed and the possible markets described. Three main challenges on the road to competiveness – lifetime, reliability, and cost – are addressed. Techno-economic studies of the different market segments are used to define the threshold for market entry. The entry ends by looking ahead and concluding that the SOFC technology is ready for the market with respect to the projected cost and lifetimes, but that reliability under real-life conditions still remains to be demonstrated. The learning investments needed, however, do not appear to be prohibitive considering the benefits which this game-changing technology has to offer.

The Global Energy Challenge

Increasing Power Demand

The increasing global demand for energy and power mainly comes from the growth in industrialization, population, and living standards.

Forecasts from International Energy Agency (IEA – all forecasts in the following comes from the publication World Energy Outlook 2010 [1]) show that the population will grow from 6.7 billion in 2008 to 8.5 billion in 2035. Almost all of the increase will take place in the non-OECD area.

On a global scale, the demand for primary energy is expected to increase by 1.2% per year until 2035. More than one third of the total primary energy consumed is used for power generation (Table 1).

The rapid population growth in the non-OECD area is further followed by a sharp increase in urbanization, which will have a significant impact on the demand for power coming from industrialization and improvements in housing and level of welfare. The demand for electricity generation will therefore increase accordingly and at an even higher rate than the energy demand. Total electricity consumption is expected to increase by 2.5% per year until 2035 (Table 2).

The growth in primary energy demand together with the decreasing accessibility of fossil fuels is expected to result in increasing energy prices. This makes efficiency in power production an important issue. Technologies with higher efficiency will be in demand.

In 2035, a very large number of people will not have access to power in the quantities known to us in the

Solid Oxide Fuel Cells, Marketing Issues. Table 2 World electricity consumption

TWh	1980	2008	2020F	2035F	Annual growth rate 2008–2035
OECD	4,739	8,244	10,339	11,566	1.0%
Non-OECD	971	7,575	12,841	18,763	3.8%
Total, world	**5,711**	**16,819**	**23,180**	**30,329**	2.5%

Solid Oxide Fuel Cells, Marketing Issues. Table 3 Projected capacity additions and investment in power infrastructure 2008–2035

	Capacity addition (GW)	Investments, new plants (billion US dollars)
OECD	1,985	3,992
Non-OECD	3,688	5,642
Total, world	**5,673**	**9,634**

OECD area today, despite the rapid growth and urbanization within the non-OECD area. Although the total power consumption is expected to double from 2008 to 2035, 38% of the world's power consumption will still be in the OECD area, having only 15% of the world population. While the per capita electricity consumption in the non-OECD countries will be doubled by 2035 to 2,600 kWh/year, it will at that time only be around one fourth of the level of the OECD area.

Significant Structural Investments Needed

In order to meet this high level of consumption, significant investments in energy production and power generation will be needed. The figure below shows the expected growth and the expected investments in power generation capacity (Table 3).

The majority of investments will take place in the non-OECD area. The total growth in capacity, including replacement and expansion, will be about 5,700 GW or almost 10 trillion US dollars over the forecasted period. This corresponds to 220-GW new capacity or investments in new plants of 370 billion US dollars per year.

The total investment in new power generation capacity constitutes more than half of the total world energy investments. This means that in future, a high dependency on the power grids remains, and the cost of improving poor grids and in establishing new grids where these do not yet exist will be significant.

Despite the expected high level of investments, the power grid and other power infrastructure will impose a limitation on the capacity and efficiency of the present infrastructure. This will be a driver toward a more decentralized power production with production taking place closer to the end user and with combined production of heat and power.

The transmission losses throughout the grid existing today will also exist in future. On a global average, the energy content of the primary fuel that is actually converted into consumed power will not exceed 35%.

Renewable-Based Power Production Increase

The increasing scarcity of oil and other fossil fuels makes the exploration efforts more expensive and the transport routes to the consumers longer. This will concentrate the remaining reserves to a limited number of countries. This is a growing concern to the net-importing Western world.

Power generation based on renewables is expected to increase over the forecasted period due to higher fossil fuel prices, growing concerns over pollution and greenhouse gas emissions, and declining technology costs and government support. Renewable electricity generation is expected to grow globally and will in the OECD area constitute 26% of the total power generation in 2035, and in the non-OECD area 22% (Table 4).

The rising share of wind and solar power (PV) poses a challenge of integration into the power grid and a challenge of how to match power production with power demand in due time. Power production from wind and PV fluctuates according to the prevailing conditions with regard to weather, season, and time of the day. Problems due to variability affecting the reliability of a power production system are manageable when the shares of wind and other variable renewable capacity are small, but with a larger share of power from renewables, such problems will increase.

This makes it necessary to balance the growth in renewables in the overall production system with

Solid Oxide Fuel Cells, Marketing Issues. Table 4 Fuel sources of power generation

TWh	1990	2008	2020F	2035F	Annual growth rate 2008–2035

smaller, scalable units capable of equalizing the fluctuations created by solar cells and wind turbines.

Restrictions on Pollution and Emissions Still Tighter

The extensive use of fossil fuel globally will continue to drive up power-generation-related CO_2 emissions, from 11.9 Gt in 2008 to 14 Gt in 2035 in the base scenario. Nearly all the increase in power-related CO_2 emissions is expected to come from non-OECD countries, where urbanization and higher living standards – together with rising reliance on fossil fuels – are particularly pronounced. The non-OECD area is projected to increase its power-related CO_2 emission by more than 50% by 2035, corresponding to 76% of the total amount.

Continuously, stricter legislation on emissions and pollution is introduced in most countries. This will be supported by incentive schemes given to energy technologies that have inherently lower emissions.

This is already the case in Europe and the USA. The high-growth countries in the Far East and South America have less focus on climate end environment at present. But along with their development, an increasing awareness of the environmental issues is expected to emerge. This will be followed by willingness and ability to pay for advanced, cleaner energy technologies.

Global Challenges

All in all, the situation can be summarized in the headlines below. The world urgently needs new technologies that can help solve the challenges of access to clean and sufficient energy (Table 5).

Fuel cells are one of the most promising technologies capable of delivering solutions to the world's energy challenges.

Briefly on the SOFC Technology

A fuel cell system produces electricity from a cleaner and more efficient fuel than conventional technologies. The fuel can be natural gas, diesel, biogas, hydrogen, or similar. Like batteries, a fuel cell generates power by an electrochemical process.

In physical terms, an SOFC fuel cell is a very thin, planar "sheet" of flexible, ceramic material consisting of three functional layers – the anode, the cathode, and the electrolyte (Figs. 1 and 2).

Fuel is supplied and passes over the anode side, and air passes over the cathode. The electrolyte – a thin, gas-tight, ion-conducting layer – is placed between the anode and the cathode.

An external circuit connects the anode to the cathode and provides the mechanism to power electrical devices (Fig. 3).

A single fuel cell can create a voltage of approximately 0.7–0.9 V.

The current state-of-the-art SOFC anode-supported cells based on doped zircona ceramic electrolytes, ceramic LSM cathodes, and Ni/YSZ cermet anodes are operated in the temperature range 700–800°C with a cell area specific resistance (ASR) of about 0.5 Ω/cm^2 at 750°C. Using the more active ceramic lanthanum

Solid Oxide Fuel Cells, Marketing Issues. Table 5 Global challenges in the energy complex

GLOBAL CHALLENGES *urge decision makers to set*	TARGETS *which will need radical*	SOLUTIONS
– Global growth in future power demand – Global warming increasing – Risk linked to accessibility and location of fossil fuels – Energy security and dependency – Balance problems in supply due to increasing renewable share – Increasing energy prices – Limited capacity and potential expansion in existing grid	– Significantly increase power output per volume of fuel input through higher efficiency – Reduce CO_2 – and other emissions – by higher efficiency and by use of emission neutral renewable fuels – Provide sufficient power for everybody everywhere	– Raising electrical efficiency – Reduction in CO_2 by change in fuels and power generation technologies – Decentralisation and scalability of power supply – Fuel flexibility and increased use of renewable fuels – Heat and power coproduction – Energy storage technology

Solid Oxide Fuel Cells, Marketing Issues. Figure 1 Electrolyte/electrode assembly

strontium cobalt ferrite (LSFC)-based cathodes, the ASR is decreased to about 0.25 Ω/cm^2 at this temperature, which is a more favorable value regarding overall stack power density and cost-effectiveness.

Fuel Cell Stack, Stack Modules, and PowerCore

Single cells are combined in a stack to generate power in useful quantities.

Solid Oxide Fuel Cells, Marketing Issues. Figure 2 Highly flexible material

Solid Oxide Fuel Cells, Marketing Issues. Figure 3
The electrochemical process of a fuel cell

A stack is a multilayer construction of fuel cells separated by metal sheets (the "interconnect plate") guiding the flow of air and fuel to the individual cells. The number of repeated cell/interconnect plates determines the stack capacity. The stack is the heart of a fuel cell system (Figs. 4 and 5).

With the current technology, a stack can generate up to about 3 kW of power. For larger power levels, stacks are combined into stack modules, which in turn also can be combined, thus providing for power output, in principle, approaching indefinite sizes.

In addition to a stack or stack module, a fuel cell system comprises components for handling of fuel, heat, electric power conditioning, and other components required for the operation.

The fuel cell process on which Topsoe Fuel Cell's technology is based (SOFC) takes place at temperatures of 700–900°C. The parts of the system operating above 300°C are integrated into a module called a PowerCore™. The PowerCore is a highly integrated "black box" with defined operating responsibility suitable for installation into complete systems (Fig. 6).

Comparing Fuel Cells to Conventional Technologies

A conventional combustion engine converts the energy stored in the fuel to electricity through a combustion, which in turn drives a generator that produces electricity. In contrast, a fuel cell converts the same initial energy into electricity via a direct electrochemical path.

This direct conversion of energy to electrical power means that fuel cells have higher energy efficiency, and at the same time, lower emissions of CO_2, VOC, and NO_X than the dominating power generation technologies based on combustion. This makes fuel

Solid Oxide Fuel Cells, Marketing Issues. Figure 4
Fuel cell stack

PowerCore™

cell technology economic and very environmentally friendly and accordingly addresses the major challenges of the energy sector: economy, securing energy supplies, and protection of the environment.

Different Types of Fuel Cells

Different types of fuel cell technologies exist. They are all based on the same electrochemical principle but differentiated by the materials used for the electrolytes. The six major types are:

- Proton exchange membrane (PEMFC)
- Alkaline (AFC)
- Phosphoric acid (PAFC)
- Molten carbonate (MCFC)
- Direct methanol (DMFC)
- Solid oxide (SOFC)

The difference in materials between the fuel cell types results in large differences in performance parameters and operational requirements. This makes the different types specifically suited for different applications.

With some exceptions, higher-temperature systems (MCFC, SOFC, PAFC) tend to be best suited for larger applications, while low-temperature systems (DMFC, PEMFC, AFC) can, in addition to units up to some hundred of kilowatts, be configured to provide as little as a few watts of power or less and hence be applied for portable equipment etc. (Fig. 7).

Advantages of SOFC Fuel Cells

Analyses made by Haldor Topsøe and Topsoe Fuel Cell have shown that SOFC technology possesses the highest potential to become a main contributor to the global power market because of:

Higher electrical efficiency. The SOFC technology will be able to provide an electrical efficiency of up to 60%. This efficiency is very high compared to worldwide power plants operating at average electric efficiencies of 30–35% and to existing decentralized, smaller power generation equipment (engines and generators) operating at as low as 5–10% for engines and 15–25% for generators. Application of SOFC units with higher electrical efficiency will result in substantial savings in fuel and money, and for operation on fossil fuels also in a proportional reduction in CO_2 emissions.

High efficiency for all capacities. The SOFC technology is scalable and can cover the complete range from 1 kW to 1 MW, or even higher, with almost no loss of efficiency. The technology offers a very competitive output per weight or volume compared to power plants. Because of this, the SOFC technology addresses a wide range of applications and finds use both in urban and remote areas and both for stationary and mobile purposes.

Fuel flexibility. The SOFC technology is (together with MCFC) the only technology among the different fuel cell technologies which is able to effectively

Solid Oxide Fuel Cells, Marketing Issues. Figure 7
Primary applications for different fuel cell technologies

generate power directly based on the fossil fuels in use today, and at the same time, the technology has a clear path to renewables and CO_2-neutral energy systems. This is due to the higher operating temperatures and the superior ability of the SOFC to convert hydrocarbon in the fuel cell stack.

Lower maintenance cost. The SOFC system provides a highly effective and direct electrochemical conversion of fuel to power. The only rotating parts in the system are a fuel pump and a small air blower. Accordingly, maintenance costs are expected to be substantially lower, and operating periods between overhauls are substantially longer than conventional technologies.

Lower emission and noise levels. Since no combustion is involved, the acoustic and heat signatures and particle (NO_X or other particles) emissions will be small. This is crucial for some applications.

Synergies with coupled technologies. SOFC systems are very well suited for integration in coupled technologies. Examples include SOFC systems with heat pumps or air-conditioning systems in which SOFC systems can produce power and interchangeable heat or cooling. SOFC can also be coupled with gas turbine to provide extremely high electrical efficiencies up to 70%.

Solid oxide electrolysis (*SOEC*). The SOFC technology deals with conversion of fuel to power. However, the system can be designed to handle the reverse process converting excess production of power to fuel (electrolysis). This is especially interesting in relation to balancing fluctuating power generating sources, like wind turbines or PV systems, but it is also of interest in relation to nuclear power plants, where change from stable base load operation to match supply and demand is not accepted. Commercialization of SOEC is still some years ahead but is an extremely important future feature of the SOFC technology, especially because SOEC is the only electrolysis technology with the capability to electrolyze CO_2 so that synthesis gas (CO plus H_2) can be produced. This opens up the possibility of production of renewable transportation fuels from power, water, and CO_2 without having to rely on limited biomass resources and renewable fuels.

Competing Conventional Power Generation Technologies

SOFC systems will, in the coming commercial phase, face competition primarily from the conventional power generation technologies such as boilers, Stirling engines, diesel generators, gas engines, batteries, etc., much more than competition from other fuel cell producers. Most of the conventional technologies are advanced, mature technologies (Fig. 8).

The fuel cell industry in general has to prove that fuel cell systems can provide superior performance (taking all technical, financial, and environmental parameters into account) compared to existing technologies.

The strength of competition from other power generation technologies differs between the different applications and markets.

Markets

Solid oxide fuel cells have a higher efficiency than existing power generation technologies, meaning that attractive and competitive applications of SOFC systems are almost endless – provided the cost and performance targets are met. This includes applications of small and large capacity, stationary and mobile applications, and centralized and decentralized applications, running on fossil fuels as well as on renewables.

Figure 9 groups the potential applications according to power range and mobility. The applications are described in more detail below.

Each market has specific requirements to the technology with regard to, e.g., capacity, cost, and lifetime. Accordingly, there will be a difference as to when the SOFC technology is ready for a given market. Some of the early opportunities, such as smaller units for military applications and secondary power, are characterized by having relatively low capacity requirements and accepting a slightly higher price compared to consumer markets.

Topsoe Fuel Cell uses a classification of the potential target applications in three generic market segments: micro-combined heat and power (micro-CHP), auxiliary power units (APU), and distributed generation (DG). In Fig. 10, the market segments are grouped following this classification.

Solid Oxide Fuel Cells, Marketing Issues. Figure 8
SOFC compared with other power production technologies (illustrative figures)

		Small 1–5 kW	Medium 5–50 kW	Large 50–250 kW	Mega large >250 kW
Stationary	Grid	– ***micro-CHP (residential)***	– ***Apartment buildings*** – ***Hotels*** – ***Small industry***	– ***Medium industry*** – ***Super markets*** – ***Hospitals***	– Power plants – Airports – Large industry – Electrolysis
	Off-grid	– ***Telecom base stations*** – Remote holiday houses	– ***Military camps*** – Emergency aid camps – Large screens, light and sound at concerts, circus etc. – Oil and gas industry (power for pipeline pumps and surveillance) – Hotels, ski lifts etc.		– Remote villages and towns – Offshore platforms
Mobile		– ***Unmanned aerial vehicles*** – ***Truck cab power*** – Recreational vehicles – Yachts – Golf cars	– ***Military vehicles*** – Buses – Range extenders (battery charger for electric battery vehicles) – Cooling containers	– Coastal vessels – Airplanes	– Trains – Ocean going vessels
SOEC (electrolysis)					– Storage for renewable energy – Smart grids – Nuclear plants

Solid Oxide Fuel Cells, Marketing Issues. Figure 9
Applications for SOFC fuel cells – Topsoe Fuel Cell target applications are highlighted

Solid Oxide Fuel Cells, Marketing Issues. Figure 10
Market segments grouped by Topsoe Fuel Cell segmentation

Topsoe Fuel Cell has chosen initially to target the markets for residential micro-CHP, smaller CHP units (up to 250 kW) within DG, and APU for trucks and military applications first because these applications pose early opportunities for demonstration and at the same time lead to high volume markets later on.

Micro-combined Heat and Power (micro-CHP)

micro-CHP units are small stationary systems with an electricity capacity of 1-5 kW intended mainly for private households. The systems are typically based on natural gas using the existing gas pipeline system.

The existing market for domestic power and hearting is dominated by gas-based systems, based on an internal combustion engine technology (ICE) or a Stirling engine. In addition, some 8,000 PEM fuel cell systems are installed in Japan, and some hundred PEM units have been sold in the USA.
